Ingram<sup>52</sup> et al<sup>53</sup> found that local reduction in cutaneous temperature facilitated the introduction of needles through the skin of children for the purpose of medication or venipuncture. They used an insulated, ice-filled copper tube, which maintained a constant temperature for several hours. Application for a few seconds produced sufficient cooling for painless skin puncture.

### Complications

Every method of effecting anesthesia for surgical procedures over an extended period of use has been accompanied by certain complications. Regional anesthesia, however, has its specific category of complications, chief among which are nerve paralyses and subarachnoid sepsis. Nicholson and Eversole<sup>54</sup> recently presented a review on the neurologic com-

plications of spinal anesthesia. Steinberg and Bishop<sup>55</sup> and Fairclough<sup>56</sup> reviewed the pathogenesis of abducens-nerve palsy after spinal anesthesia, and Rose and Pritzker<sup>57</sup> reported a recent case. Evans<sup>58</sup> collected a number of cases of meningitis following spinal anesthesia and outlined a technic for prevention. Kennedy et al<sup>59</sup> described 3 cases of fibrinous arachnoiditis after spinal anesthesia. Chivers<sup>60</sup> reported that the incidence of pneumothorax with intercostal nerve block was 19 per cent.

### REPLACEMENT THERAPY

That a real need exists for better methods of evaluating the effectiveness of modern preoperative preparation of the poor-risk surgical patient is keenly appreciated by both the surgeon and the anesthetist. Too often, a patient who is considered adequately prepared shows signs of shock in the operating room or develops a serious postoperative surgical complication. Recently, attention has been directed to the decreased blood volume in these chronically ill patients. Lyons et al<sup>61-63</sup> introduced the term "chronic shock" to describe this condition. The complete syndrome consists of weight loss, decreased blood volume, decreased blood protein and increased interstitial fluid volume. The authors showed that weight loss was correlated with reduced total mass of blood proteins without significant alteration of blood protein concentration. Lowering of the total hemoglobin mass, as in chronic bleeding, leads to the loss of plasma from the vascular bed to the interstitial fluid compartment. A reduction in plasma volume, as well as a loss of total hemoglobin, may mask deficiencies in the total mass of blood proteins. Ordinary methods of blood determinations, they contend, will then fail to show the reduction of blood volume and the attendant increased susceptibility to shock. Lyons et al<sup>64</sup> stated that corrective therapy consisted of whole-blood transfusion. In their studies adequate correction of chronic shock necessitated an average of 2700 cc of blood in the preoperative period. After such treatment the plasma-volume increase approximates but rarely equals or exceeds the gain in erythrocyte volume. Consequently, the restoration of the hematocrit value to 50 per cent was advocated as an index of adequate therapy. A fundamental disturbance in hemoglobin metabolism was shown to be present in patients suffering from cancer.

Davidson and his associates<sup>65</sup> studied blood changes in patients with acute medical illnesses. They found that patients exhibiting peripheral vascular collapse had hyperglycemia, lactic acidemia and a decrease in the bicarbonate reserve. There was also usually a lengthening of the prothrombin time and an elevation of the icteric index.

Scheinberg et al<sup>66</sup> reported on homologous serum jaundice and warned against injudicious use of blood plasma from pooled lots.

## SUMMARY

The medical literature since World War II has introduced many new advances in regional anesthesia. Segmental spinal anesthesia and the addition of vasopressor drugs to agents used for spinal anesthesia are advocated as aids in decreasing the concentration and total amount of spinal drug necessary. Better control of the hypotension seen with spinal anesthesia is offered by new vasopressor drugs. The investigation of synthetic hypnotics gives promise of better preoperative and postoperative management of the surgical patient's apprehension and pain. Sympathetic-nerve block has proved an effective therapeutic agent in many disorders heretofore uncontrollable. The use of weighted spinal-anesthetic solutions for vaginal delivery offers a safer agent for obstetric anesthesia, and finally, the recognition of the serious depletion of whole blood volume in chronically ill patients throws new light on the preoperative preparation of this group.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

### Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

### CASE 34191

#### PRESENTATION OF CASE

**First admission.** A twenty-seven-year-old housewife entered the hospital because of shortness of breath.

This symptom had bothered her as long as she could remember. She had always restricted her activities and found running impossible. She slept propped up on at least two pillows and had often been aware that the heart beat forcefully. Dyspnea and orthopnea became gradually severer during the two years before admission, and several new symptoms developed. These consisted of a dull ache to the left of the sternum, at first only after eating and then almost constantly, ankle swelling after standing for any length of time and cyanosis of the face, lips and fingernails aggravated by exertion. Two months before admission a new type of chest pain was noted, a constricting sensation beneath the sternum, associated with exertion, disappearing on rest and nonradiating. During the month before admission the patient was confined to bed

with a respiratory infection. She entered the hospital because of failure to improve.

There was no history of rheumatic fever or other heart disease. Upper respiratory infections were frequent during the winter prior to admission, and the patient was bothered by a chronic, dry cough. There was no history of hemoptysis, night sweats or pleural pain. Seventeen years before admission she had entered the hospital because of polyuria and polydipsia. Physical examination was essentially negative. The chest was clear, and the heart sounds were unremarkable except that the pulmonary second sound was split and the same double sound was heard at the apex but to a less marked degree. No murmurs were heard. Examination of the blood was negative. The urine was not remarkable, except that the specific gravity seldom exceeded 1.002. A diagnosis of diabetes insipidus was made, and the patient was given surgical pituitrin, which controlled the symptoms. At home she continued the drug, two or three injections a day for fifteen years until two years before the present admission, when this treatment was stopped and the symptoms did not recur. The onset of catamenia had been very irregular. She had been married twice but had never become pregnant.

Physical examination showed an intensely cyanotic, rather obese woman lying propped up in bed. The veins of the fundi were tortuous and engorged, although the neck veins were not distended. The chest was clear to percussion and auscultation. The left border of cardiac dullness was at the midclavicular line, the right border was not percussible. The most forceful impulse was in the third and fourth left interspaces, it was much stronger than the apical beat. The pulmonary second sound was very loud and the pulmonary first sound

moderately so, and the other heart sounds were distant. There was a soft, short diastolic murmur best heard in the third left interspace. The abdomen was obese and showed striae, and palpation revealed tenderness in the right lower quadrant. No organs or masses were felt. There were clubbing and cyanosis of the fingers and toes.

The temperature and pulse were normal. The respirations were 40. The blood pressure was 108 systolic, 80 diastolic.

The urine gave a +++ test for albumin and had a specific gravity of 1.006, the sediment contained epithelial cells. The red-cell count was 8,450,000, the hemoglobin 18.5 gm, and the white-cell count 9550. The fasting blood sugar, the nonprotein nitrogen, the carbon dioxide, the total protein, the sodium and the chloride were all within normal limits. The venous pressure was equivalent to 120 mm of water, the circulation time was 8 seconds with ether and 30 seconds with decholin. An x-ray film of the chest showed enlargement in the region of the left auricle and ventricle. The pulmonary artery and lung roots were prominent. An electrocardiogram revealed sinus rhythm, with a rate of 85, and a PR interval of 0.24 second, a QRS complex of 0.09 second, normal voltage, right-axis deviation, a slurred R wave in Lead 2, sagging ST segments in Leads 2 and 3, flat T waves in Leads 1 and 2, a very low T wave in Lead 3 and sagging ST segments in Leads CF<sub>1</sub>, CF<sub>4</sub> and CF<sub>6</sub>, with a prominent S wave in Lead CF<sub>1</sub> and inverted CF<sub>1</sub>, CF<sub>4</sub> and CF<sub>6</sub>. The patient improved on small venesections, digitalis and ammonium chloride. She was discharged on a low-sodium diet to be followed in the Cardiac Clinic.

*Second admission* (two months later). The patient did well on markedly limited activity until two months later, when she had an attack of breathlessness and substernal pain and was readmitted to the Emergency Ward. The physical findings had not changed. The diastolic murmur was described as a rumble, and an early diastolic blow was heard in the second left interspace. She improved on aminophyllin and was discharged after a two-day stay.

*Third admission* (five months later). During the period after discharge she was treated with venesection on several occasions, which lessened the symptoms. During the five days before re-entry she had three attacks of severe, stabbing pain in the left breast. Nausea, vomiting and great anxiety were also prominent symptoms.

Physical examination revealed an extremely agitated, cyanotic woman, lying flat on a stretcher. The pulse rate was 100, and the respirations 40. The blood pressure was 80 systolic, 60 diastolic. There was no venous distention with the patient sitting up. The chest was clear, and the heart unchanged. The liver edge was not felt. Five hours later the patient was examined by a consultant,

who found in addition to the above findings a protodiastolic gallop and many dry, crepitant rales. Pressure on the right upper quadrant did not distend the cervical veins or reveal pulsations, but while this procedure was being done the patient suddenly stopped breathing, became pulseless and died.

#### DIFFERENTIAL DIAGNOSIS

DR HOWARD B. SPRAGUE: May we see the x-ray films?

DR STANLEY M. WYMAN: The heart shadow is enlarged as described in the record. The left auricle appears to have displaced the left main-stem bronchus upward and to have narrowed it slightly. The enlargement of the left auricle is seen in the oblique view, I do not believe that I can say whether the enlargement of the ventricles is to the left or the right from the films alone. The heart comes far forward to the chest wall, strongly suggesting that the right ventricle might be large, and far posteriorly, which makes one question the left ventricle also. The main pulmonary artery is strikingly prominent in the anteroposterior projection, and the left and right main pulmonary arteries are more prominent than usual. The aorta is small. The lung fields are essentially clear. There is no evidence of pleural fluid.

DR SPRAGUE: There is no pulmonary lesion that you can find, except vascular?

DR WYMAN: I see no localized pulmonary disease. I cannot detect any intracardiac calcification on the films. I do not know about fluoroscopy.

DR SPRAGUE: The right-axis deviation in the electrocardiogram is an important finding. It tends to contradict the observation of the left ventricular enlargement by x-ray examination.

I am going to start by saying that this is a case of pulmonary hypertension and see where we can go from there. The chronology is important. This woman had been dyspneic all her life, which is in favor of some type of congenital lesion, cardiac or pulmonary. At the age of ten years the examination showed no cyanosis or clubbing, no heart murmurs and no other cardiac abnormalities, except for a split second sound at the pulmonary area, and a negative blood examination. At the age of twenty-five dyspnea and orthopnea had increased and a dull ache developed at the left of the sternum, with ankle swelling on standing, cyanosis of the face, lips and fingernails, worse on exertion, and chronic dry cough. At twenty-seven years of age the patient entered the hospital, and examination showed obesity, intense cyanosis, a forceful impulse in the left third and fourth spaces, a loud pulmonic second sound, a soft diastolic murmur along the left upper sternal border and clubbing of the fingers and toes. Is there any note about the degree of clubbing?

DR. TRACY B. MALLORY: It was rather severe clubbing.

DR. SPRAGUE: The significant laboratory findings are a red-cell count of 8,500,000, with a hemoglobin of 18.5 gm., somewhat increased venous pressure with normal arm-to-lung but prolonged arm-to-tongue circulation time. Of course this chronology rules out at once the congenital cardiac conditions associated with cyanosis and death in early life because this is primarily a patient with delayed cyanosis, and for that reason I have to assume that there was some change in the pressure relations in the circulation if we are going to invoke a veno-arterial shunt. There may previously have been an arteriovenous shunt, but whether or not we invoke this change in circulatory dynamics the evidence does point toward changes in the pulmonary circulation as being most important. If we assume that there was a congenital cardiac condition, what are the arteriovenous shunts not associated with cyanosis in early life, that may become veno-arterial shunts if there is a change in the pressure relations? One should mention interauricular septal defect, with or without mitral stenosis congenita or acquired—a Lutembacher syndrome, a high interventricular septal defect, patent ductus arteriosus, and, finally, Eisenmenger's complex. Regarding the pulmonary conditions, if we assume that we are dealing primarily with a pulmonary situation, with secondary cardiac changes of cor pulmonale, there may have been congenital anomaly, hypoplasia of the vascular tree or a change of some sort in the endothelium of the arterioles or capillaries. There may have been endarteritis or possibly secondary changes in the pulmonary circuit due to prolonged arteriovenous communication as in some cases of patent ductus, which transposes the systemic pressure to the pulmonary side and results in changes in the lung vessels, causing delayed increase in pulmonary blood pressure. Finally, there are the unexplained changes in the lung of the Eisenmenger complex. In that condition there are a dextroposed aorta, a high interventricular septal defect and a large pulmonary artery as contrasted with the small pulmonary artery of the tetralogy of Fallot. In the Eisenmenger complex there is no obstruction in the outflow tract of the right side of the heart, but increased peripheral resistance in the lung, and little or no cyanosis, or delayed cyanosis. I think this development of heart symptoms with severe compensatory polycythemia and chest pain can be interpreted under the term of "angina hypercyanotica," which is described in conditions of high pulmonary pressure and polycythemia although in this case I cannot rule out some degree of coronary insufficiency. Against interventricular septal defect, with or without mitral stenosis, clinically, is the fact that this woman was obese. These patients tend to be of slight build. There was not the striking increase

in the pulmonary vascular markings typically associated with an interauricular septal defect, in which there is tremendous increase in the pulmonary flow. Furthermore, in interauricular septal defect the cyanosis—the "cyanose tardive" of the French—is not of long enough duration before death to be associated ordinarily with clubbing of the fingers. In interauricular septal defects one frequently sees auricular fibrillation, and, furthermore, there was no history in this case of rheumatic infection, which patients with interauricular septal defect are very prone to have.

As against uncomplicated high interventricular septal defect, I am worried about the absence of a systolic murmur because the condition is clinically associated with a loud systolic murmur and thrill. Against patent ductus arteriosus, again, is the absence of anything characteristic of the continuous murmur of patent ductus arteriosus. Against the Eisenmenger complex again there is no evidence of interventricular septal defect. There was no murmur, and although a soft early diastolic murmur had developed along the left sternal border, I am more willing to call that a functional murmur, a Graham-Steell murmur, rather than that of aortic regurgitation, which may be found with the Eisenmenger complex, because the aortic valve may be involved in the anomaly high up in the septum.

The evidence for primary pulmonary disease of the small arterioles is that the findings were those of dyspnea without diagnostic murmurs, and I might be inclined to think that we are dealing with a congenital vascular anomaly of the pulmonary bed. I believe that with such a condition the patient would not have gone so long as this without cyanosis and failure.

The lack of support for the diagnosis of veno-arterial shunt is the prolonged arm-to-tongue time. If something is injected into the vein and goes from the right side of the heart immediately over to the aorta, there should be shortening of the circulation time to the tongue. On the other hand, there may be such a slight venoarterial shunt that that is not good evidence. In this sort of situation Taussig<sup>1</sup> has recently emphasized the trial of inhalation of oxygen as being diagnostically valuable because if the cyanosis is due to a pulmonary condition, it may disappear. But in the Eisenmenger complex the oxygen saturation of the arterial blood will not be normal because there is still some degree of shunt of venous blood between the right ventricle and the aorta.

The events in the last seven months of the patient's history are attacks of breathlessness and substernal pain and what is described as a diastolic rumble. I do not know whether that has been added to make one think this was a Lutembacher syndrome with mitral stenosis, or whether it was an interpretation of one observer of what was later

called a gallop rhythm, perhaps gallop rhythm of the right ventricle. The final severe stabbing pain in the left breast, the fall in pressure, the absence of venous distention and the sudden death could have been due to either coronary-artery or pulmonary failure.

In summarizing this rather complicated situation, what do we have as possibilities? I should say primary pulmonary vascular anomaly that the patient had had all her life. There is no reason to consider that she represents the type of patient we have seen in these sessions in whom there has been pulmonary endarteritis or an obstruction of the finer vascular radicles. There are cases of multiple emboli, such as those described by Castleman and Bland<sup>2</sup>. The symptom of dyspnea in this case, however, was present all her life. Any arteriovenous shunt, I think, may well lead to greater pressure strain on the lesser circulation relative to that on the systemic. Volume strain is usually tolerated better than pressure strain on the pulmonary circuit. However, when these conditions exist more changes in the pulmonary vessels may ensue. These, in turn, increase the pulmonary pressure and result in reversal of an arteriovenous shunt, as in interauricular or interventricular septal defect, or even patent ductus arteriosus. That possibility has been advanced recently as another reason for ligation of patent ductus arteriosus.

I do not believe that we are dealing with idiopathic pulmonary fibrosis with cor pulmonale, but I confess that we have little evidence beyond the long history and delayed cyanosis to support a diagnosis of Eisenmenger's complex, mostly because of the absence of murmur. Yet we have certain cases of tetralogy of Fallot in which there is also an interventricular septal defect without a systolic murmur. I think that can be explained only by the fact that there may be only a small pressure gradient between the right and left ventricles, and murmurs are suppressed by increased blood viscosity from the polycythemia.

That brings us to what happens in the lung in the Eisenmenger complex. With a large pulmonary artery and an interventricular septal defect one would expect that the blood from the right side of the heart would readily pass into the pulmonary artery and not go into the left side of the heart and aorta to cause cyanosis. That is what happens in early life, but for some reason this increase in peripheral resistance in the lung occurs and cyanosis develops, mainly because of faulty oxygenation in the lung and also because of venous admixture through the ventricular septal defect. I am therefore going to vote for a combination consisting of a dextroposition of the aorta, explaining perhaps the small aortic shadow, the large pulmonary artery and a high interventricular septal defect. Thrombosis probably occurred in the pulmonary vessels. I cannot say just what may be found

anatomically in these vessels, but there will be some type of abnormality. The patient probably had some coronary insufficiency, either from anoxemia and increased blood viscosity, in addition to what was a real anemia after the venesections, or from functional pulmonary-valve regurgitation, which the pathologist will probably not be able to prove.

DR MALLORY I take it you are not interested in the diabetes insipidus?

DR SPRAGUE It did bother me, but I cannot fit it in except as a manifestation of another congenital anomaly, although we have no history of any familial incidence.

DR JOSEPH AUB I am interested by the fact that when the patient was ten years old there was no suggestion of cyanosis.

DR SPRAGUE She had an increased pulmonary second sound and was unable to breathe comfortably.

DR AUB The same thing that was bothering the pulmonary vessels may have bothered the pituitary vessels when she was ten. How is that?

DR SPRAGUE Good.

DR AUB Then the whole thing would have been vascular.

DR SPRAGUE She pulled through the diabetes insipidus.

DR AUB. She had extensive circulation.

A PHYSICIAN How do you explain the increased PR interval?

DR SPRAGUE I think that the increased PR interval was nonspecific.

#### CLINICAL DIAGNOSES

Congenital heart disease, incompletely diagnosed  
Pulmonary endarteritis?

#### DR SPRAGUE'S DIAGNOSES

Interventricular septal defect.  
Dextroposition of aorta.  
Thrombosis of pulmonary vessels, probable

#### ANATOMICAL DIAGNOSES

*Pulmonary fibrosis and emphysema, with slight bronchiectasis*  
*Cor pulmonale*  
Hydrothorax, bilateral  
Chronic passive congestion  
Pulmonary arteriosclerosis, slight  
Hyperplasia of bone marrow  
Adenoma of thyroid gland

#### PATHOLOGICAL DISCUSSION

DR MALLORY I have to present my evidence visually—otherwise you will not believe me. We found a marked cor pulmonale. The heart weighed 450 gm. The right ventricle was almost as large as the left, measuring 12 mm in thickness. There were no congenital abnormalities of any sort.

The lungs, in contrast, showed a diffuse fibrosis and emphysema (Fig 1). Here is a focal granuloma in the lung with numerous foreign-body giant cells, faintly suggestive of sarcoid (Fig 2). Here is an area of bronchiectasis surrounded by rather extensive bands of fibrosis. I think this case is one of true cor pulmonale. What the explanation of the pulmonary changes remains very much more of a problem. The patient was very young to have a severe emphysema. When we do see it in young people it is usually associated with evidence of some destructive fibrotic process that has occurred in the past. One group of such cases that we have

FIGURE 1

recently been interested in here shows multiple sarcoid-like lesions throughout the lung. The evidence for that is minimal in the case under discussion. There were a small number of lesions such as the one I showed that suggested it, but if there ever was an extensive process of that sort, it had almost completely healed. It is also rather mysterious that there was no x-ray evidence of extensive pulmonary changes. The pulmonary vessels showed a few patches of atheroma but no narrowing of the vascular lumens. The bone marrow showed red-cell hyperplasia due to anoxemia, and there was a small coincidental adenoma of the thyroid gland.

DR. SPRAGUE: I have seen that and have been impressed with what we call idiopathic pulmonary fibrosis and emphysema, with absolutely normal chest films. It may be that the changes in the lung were on a congenital basis.

DR. MALLORY: No, I think they were acquired

DR. SPRAGUE: As long ago as the patient could remember?

DR. MALLORY: Yes.

DR. AUB: Then how about the pituitary body?

DR. MALLORY: It showed extensive atrophy of the posterior lobe, quite characteristic of what is

FIGURE 2

seen in diabetes insipidus. Why she should recover I cannot understand, because she had almost no posterior lobe left.

#### CASE 34192

##### PRESENTATION OF CASE

A fifty-two-year-old nulliparous housewife entered the hospital because of weakness and fatigability, pain in the left arm and leg, tinnitus, deafness and difficulty in swallowing and talking.

Fatigue and dyspnea were first noted two years before entry and became progressively worse. For several months the patient was able to perform only a minimal amount of housework. During the same period she had almost continuous severe steady pain in the left arm and "over the breast" associated with a sensation of coldness. Four months before admission there was a rapid change in the character and severity of the pain. The entire left side of the body became involved in an agonizing pain, constantly running up and down the left side of the body. Coincident with this

change in the pain there was a constant ringing in both ears, and three months later hearing became impaired. The tinnitus gradually lessened and on admission was entirely absent. There had not been any vertigo or nausea. During the few weeks before admission, while in another hospital, the patient developed a rapidly progressive weakness of the right facial nerve and difficulty in swallowing and talking. While there she required tube and intravenous feedings.

Physical examination revealed a thin, debilitated and dehydrated woman, who was alert and oriented. The heart, lungs and abdomen were normal. All four extremities could be moved equally, though feebly, and she could walk with assistance. The fundi were normal. The right pupil was 3 mm and the left 2 mm in diameter, both reacted to light. There was no nystagmus. There was palsy of the left external rectus and superior oblique muscles. The left palpebral fissure was narrower than the right. There was bilateral paralysis of masseter and pterygoid muscles and sensory loss in the left facial nerve, with a diminished corneal reflex and conjunctivitis of the left eye. Motion in the right lower part of the face was absent, and on the left was limited to a feeble upward twitch of the corner of the mouth. The sense of taste was lost. There was gross diminution of hearing bilaterally. Bone conduction was greater than air conduction. The Weber test was negative. The gag reflex was absent, and the patient was unable to swallow. There were marked weakness and slight atrophy of the tongue. The deep tendon reflexes of the arms were hyperactive, more so on the left. They were absent in the legs. The abdominal reflexes were absent, and the plantar reflexes were normal. Stereognosis and vibration sense were normal bilaterally.

The temperature was 98°F, the pulse 90 (equal and synchronous), and the respirations 25. The blood pressure was 178 systolic, 110 diastolic.

Examination of the blood at the other hospital just before admission disclosed a red-cell count of 5,000,000, with a hemoglobin of 13.2 gm, and a white-cell count of 6400, with 68 per cent neutrophils. The urine was normal. The blood sugar was 130 mg, and the nonprotein nitrogen 33 mg per 100 cc. The sedimentation rate was 85 mm per hour. A lumbar puncture done three weeks before entry showed an initial pressure equivalent to 200 mm of water, which rose to 240 mm on jugular compression and fell to 120 mm after re-

moval of slightly xanthochromic fluid, which contained 5 lymphocytes per cubic millimeter and gave a total protein of 250 mg per 100 cc with a +++ Pandy test. Ten days later the initial spinal-fluid pressure was equivalent to 290 mm of water, with a protein of 500 mg per 100 cc, a ++++ Pandy test and 18 lymphocytes per cubic millimeter.

On the first night the patient became very noisy and apprehensive and was given paraldehyde by rectum. A few hours later the respirations suddenly fell to 6 per minute. Oxygen was given by a Boothby mask. The temperature remained normal. The patient died in respiratory failure twenty-four hours after admission.

### DIFFERENTIAL DIAGNOSIS

DR. ROY L. SWANK\* Stereognosis and vibration sense were normal bilaterally, but we are not told about other sensations. Should we assume that they were normal?

DR. CHARLES S. KUBIK The sensations of touch and pinprick were said to be normal.

DR. SWANK I believe that the patient had a lesion in the brain stem or the cranial nerves emanating from it, or both, from the level of the fourth or fifth to the twelfth cranial nerve. This was certainly not a typical acoustic neuroma, although it may have been very atypical or bilateral. There are certain features that, in my mind, rule out these diagnoses: the absence of nystagmus, the absence of history of staggering or ataxia, the absence of papilledema and the order in which the symptoms developed. I also feel the same about other single tumors outside the medulla and pons in the posterior fossa. I am unable to make such a diagnosis.

Other extramedullary conditions are suggested by the fact that the patient experienced vertigo and dyspnea two years before entry, by the findings relative to the ear and by the sedimentation rate of 85 mm per hour. The white-cell count was normal, however, and there was no significant increase in neutrophils. I wonder if we are dealing with a chronic basilar meningitis. Tuberculosis would have to be thought of. Could it have been present for two years? There is no history of cough, and no report of x-ray studies. It seems unlikely that active tuberculosis was present so long. There is no history of treatment with streptomycin, which might have altered the story. I am inclined to

\*Assistant visiting neurologist, Boston City Hospital.

discard this diagnosis. Was an x-ray film taken of the chest?

DR. KUBIK: X-ray studies were not done in this hospital.

DR. SWANK: Chronic, nonspecific, basilar meningitis associated with chronic middle-ear disease is another possibility. One would have to assume that the middle-ear disease was bilateral. I consider this a difficult diagnosis to arrive at from the information at hand.

This brings me to two diagnoses, which I shall consider seriously. The first is a glioma of the pons. This is a slowly progressive condition involving the cranial nerves late and producing increase in cranial pressure late, if at all. I believe that this diagnosis is possible. The few cases of this condition that I have seen have had marked ataxia and nystagmus. I see no reason why this condition might not pick out other systems in the brain stem, however. A glioma of the pons must extend from the lower end of the medulla to the upper pons and probably the lower midportion of the brain on the left. There are several things that are difficult to explain on this basis. It leaves me unable to account for the findings relative to the ear. Bone conduction was greater than air conduction. To explain this I assume that the patient was grossly deaf and was not hearing the tuning fork, but feeling it. Also, unnnit of the prominence described in this case is unusual in intramedullary lesions. The spinal-fluid protein was markedly elevated, much more than it usually is in glioma of the pons, I shall assume that a block had occurred late in the disease and that the elevated protein content was a result of the block. Had the puncture been done some months earlier, normal protein might have been present.

Lastly, I think it is necessary to consider a malignant tumor with metastases. Metastases to the dura and to the sheaths of the cranial nerves could produce the clinical picture under discussion. Symptoms due to this lesion may be difficult to understand even after post-mortem examination. If the history is correct, one must assume that the metastases were present for two years and also that the primary site, most likely the lungs, was overlooked. It seems to me that this history was very long for dural metastases. I would consider metastatic carcinoma an attractive diagnosis but not possible to arrive at under the circumstances.

As a most likely diagnosis in this case I have to fall back on tumor within the pons and medulla, a glioma. I am not happy about it, but I believe that it has the fewest objectionable features.

DR. AUGUSTUS ROSE: I am interested in the severe pain on the left side of the body, and I wonder if Dr. Swank would assume that that was "thalamic" pain.

DR. SWANK: That has been seriously considered because it is difficult to explain the pain on the basis of a lesion in the medulla or pons. If one assumes that it was thalamic, one also assumes that there were two separate lesions and that the third-nerve nucleus was missed. I believe that this is unlikely. The smaller pupil and the drooped lid might indicate third-nerve involvement. I consider it more likely that this was due to a lesion within the brain stem producing a mild Horner's syndrome. Conditions such as syringomyelia are apt to cause pain within the spinal cord, and perhaps a similar mechanism operated in the brain stem in this case.

#### CLINICAL DIAGNOSIS

Amiotrophic lateral sclerosis

#### DR. SWANK'S DIAGNOSIS

Glioma of pons and medulla

#### ANATOMICAL DIAGNOSIS

*Metastatic adenocarcinoma, primary site undiscov-  
ered*

#### PATHOLOGICAL DISCUSSION

DR. KUBIK: I should like to say that this is probably one of the most difficult neurologic cases that has been presented here. Dr. Swank came very close to the diagnosis when he suggested the possibility of metastases. There was an unusual type of metastasis, consisting of carcinomatous invasion of the subarachnoid space with involvement of the cranial and spinal nerves. The metastatic tumor was made up of columnar cells, which formed perfect tubules and also spread out in a single layer, covering the inner surface of the arachnoid membrane, blood vessels and cranial and spinal nerves in a most unusual and fascinating way. There was invasion of the cranial and spinal nerves and slight subpial invasion of the cord and medulla. In spite of a complete autopsy, no primary tumor was found. I cannot believe, however, that a neoplasm of this type could have been primary in the central nervous system, and I assume that the primary lesion was so small that it was overlooked. We have had two or three other cases of metastatic carcinomatosis of the subarachnoid space, though none with such extensive paralyzes as this. In at least one case there were cells in the cerebrospinal fluid, and a clinical diagnosis of tuberculous meningitis had been made.

change in the pain there was a constant ringing in both ears, and three months later hearing became impaired. The tinnitus gradually lessened and on admission was entirely absent. There had not been any vertigo or nausea. During the few weeks before admission, while in another hospital, the patient developed a rapidly progressive weakness of the right facial nerve and difficulty in swallowing and talking. While there she required tube and intravenous feedings.

Physical examination revealed a thin, debilitated and dehydrated woman, who was alert and oriented. The heart, lungs and abdomen were normal. All four extremities could be moved equally, though feebly, and she could walk with assistance. The fundi were normal. The right pupil was 3 mm and the left 2 mm in diameter, both reacted to light. There was no nystagmus. There was palsy of the left external rectus and superior oblique muscles. The left palpebral fissure was narrower than the right. There were bilateral paralysis of masseter and pterygoid muscles and sensory loss in the left facial nerve, with a diminished corneal reflex and conjunctivitis of the left eye. Motion in the right lower part of the face was absent, and on the left was limited to a feeble upward twitch of the corner of the mouth. The sense of taste was lost. There was gross diminution of hearing bilaterally. Bone conduction was greater than air conduction. The Weber test was negative. The gag reflex was absent, and the patient was unable to swallow. There were marked weakness and slight atrophy of the tongue. The deep tendon reflexes of the arms were hyperactive, more so on the left. They were absent in the legs. The abdominal reflexes were absent, and the plantar reflexes were normal. Stereognosis and vibration sense were normal bilaterally.

The temperature was 98°F, the pulse 90 (equal and synchronous), and the respirations 25. The blood pressure was 178 systolic, 110 diastolic.

Examination of the blood at the other hospital just before admission disclosed a red-cell count of 5,000,000, with a hemoglobin of 13.2 gm, and a white-cell count of 6400, with 68 per cent neutrophils. The urine was normal. The blood sugar was 130 mg, and the nonprotein nitrogen 33 mg per 100 cc. The sedimentation rate was 85 mm per hour. A lumbar puncture done three weeks before entry showed an initial pressure equivalent to 200 mm of water, which rose to 240 mm on jugular compression and fell to 120 mm after re-

moval of slightly xanthochromic fluid, which contained 5 lymphocytes per cubic millimeter and gave a total protein of 250 mg per 100 cc with a +++ Pandy test. Ten days later the initial spinal-fluid pressure was equivalent to 290 mm of water, with a protein of 500 mg per 100 cc, a ++++ Pandy test and 18 lymphocytes per cubic millimeter.

On the first night the patient became very noisy and apprehensive and was given paraldehyde by rectum. A few hours later the respirations suddenly fell to 6 per minute. ## OFT IN THE STILLY NIGHT —

THE public, according to complaints received by the American Medical Association, believes that it is not getting the service it requires from its doctors. A particular grievance is the difficulty — on occasions the impossibility — of obtaining emergency medical service at night.

For various reasons a reactionary attitude toward self-sacrifice has set in since the war. The devotion to a common cause in those soul-trying years elevated many persons to a heroic state of mind. Now, at least in this country, "we the people" are demanding the pay-off. We want things material, and we want them now.

The medical profession must bear its share of this failure to see eye to eye and clearly. In too many phases of its work there has been an increasing divergence from the public interest rather than an improved cordiality in public relations. The trend toward socialization has been a trend also toward the impersonalization of medical service.

During the war, 60 per cent of the nation's physicians — and they comprised the older group — remained at home, assuming their absent colleagues' duties. They were, on the whole, overworked, but, on the whole, as old-timers they accepted the responsibilities that appeared to them to be part of the obligations of a career of service. Many of them now believe that others should bear the extra burden, and this is what the others seem unwilling to undertake. The youngsters seem to have failed to acquire the idea that they have accepted a calling.

If an obligation implicit in the practice of medicine now fails of spontaneous fulfillment, however, some organized measures must be taken to provide what is lacking. The American Medical Association suggests that county medical societies or urban groups maintain telephone exchanges that will accept the responsibility for locating physicians available for emergency calls.

The majority of the older practitioners have led lives so organized that they were never, year after year, "off call" without a substitute constantly available. It is one of the responsibilities that those who care for the sick have accepted and must continue to accept: those for whom they care must never be abandoned.

## CRUSADE FOR CHILDREN

UNDER the banner of the Crusade for Children the United Nations Appeal for Children is conducting a campaign for voluntary contributions to relieve the suffering of starving children overseas. Of the national goal of \$60,000,000, Massachusetts has been assigned a quota of \$2,500,000, with \$1,500,000 to be raised in the Greater Boston area. The funds will be distributed to twenty-six religious, labor and special relief groups to supplement the inadequate amounts that governments are presently able to appropriate for relief. These agencies include the In-

ternational Children's Emergency Fund, previously separately engaged in collecting money, which has now joined them in the united appeal

The Crusade for Children is more than another campaign to persuade hard-pressed Americans to dig into their pockets for a "worthy cause." The appeal focuses attention on the plight of the children of Europe, too often overlooked in the dramatic and uncertain political situation. These children are in acute need, and quick and generous action is required to prevent the threatened disease, mental deterioration and actual death from starvation. An example of one phase of the desperate condition of European children is provided by a recent statement from the International Children's Emergency Fund which pointed out that hundreds of thousands of infants and young children are getting no milk and that others, more fortunate, are limited to less than half a pint daily.\* The Fund has been engaged in feeding nearly 4,000,000 children in twelve European countries, and extension of the aid to Germany and China is under consideration, in co-operation with the World Health Organization and the Danish Red Cross and its Scandinavian associates, the Fund is prepared to assist governments in mass-vaccination programs to check the spread of tuberculosis among the children of Europe. To these endeavors the Crusade for Children has now added the goal of saving 230,000,000 children from starvation and death.

In 1212 A.D. the children of Europe set out on the disastrous Children's Crusade to recover the Holy Sepulcher from the infidel. It is fitting that the present campaign should take the form of a crusade for children reversing the unhappy sequel to that crusade of long ago, Americans can help give enough to keep the children of Europe alive and to give them the chance of growing up healthy in mind and body. A generous contribution today may

save tomorrow's world.

\*Release from United Nations International Children's Emergency Fund dated March 2, 1948.

### "YOUR WITNESS"

A doctor's failure to give his patient at least the degree of care and skill that is ordinarily used in his community is malpractice in the eyes of the law, and civil law requires that a patient be

recompensed for the actual damage suffered from such malpractice. Whoever professes to see anything unfair about that should be thankful that he is not living in the time of Hammurabi (about [2100] B.C.), when the law required decapitation of the doctor whose patient's illness failed to respond favorably to treatment. How bitterly must the Babylonian patient of that day have regretted his doctor's very natural reluctance to undertake a cure, and with what alarm must he have viewed the increasing shortage of physicians! Forty centuries have improved conditions, but not to the point where all criticism has disappeared.

The press, the public and the legal profession point to what they consider a seriously weak spot in the doctor's reputation for unselfish public service. They say that doctors will not testify in court "against each other." They even say that it is hard to get doctors to testify "for each other." In fact, doctors do not like to go to court at all. As a result, many malpractice suits are said to be decided by juries whose only expert testimony comes from medical crackpots and disreputable hired quacks. If any or all of this is true it must be corrected.

It should at once be admitted that most doctors are reluctant to go to court, and the validity of some of their reasons should be examined. Doctors like to think of their time as more valuable than that of other people, but courts go out of their way to save a busy doctor's time. Doctors dislike the risk of being made monkeys of by belligerent attorneys, but no witness who avoids bumptiousness and confines himself to giving honest answers need fear a hostile attorney. Nobody likes the idea of testifying against his friends, but that is not what an expert witness is required to do. His obligation is to testify to the honest truth and let the jury worry about who gets hit.

And there are two sides to it. Court procedure, even now, retains some flavor of the medieval trials by battle in which plaintiff and defendant were represented by armed champions who slugged it out with more enthusiasm for winning than for establishing the truth of a claim. As expert witnesses physicians might feel easier in the kindly hands of the judge than under the practiced battle-

axes of the contending attorneys. No perfection is claimed for medicine, and there is no reason to believe that the law is perfect. Nevertheless, it would be extremely difficult to conceive of any law that would enable juries to decide medical cases fairly without the benefit of honest medical testimony and plenty of it.

This is no private matter that can be shrugged off. Doctors are news, particularly now when the right of organized medicine to manage its own affairs is being publicly questioned on economic grounds. This is no time for doctors to let the public say that it is being defrauded of its civil rights by a polite conspiracy of silence in the medical profession. Some modern Hammurabi might believe it and get the urge to dust off one of those old laws. Any thoughtful doctor would prefer to settle for an occasional morning in court.

## MOSELEY PROFESSOR OF SURGERY

DR FRANCIS D MOORE, of Boston, has been appointed Moseley Professor of Surgery at Harvard Medical School and surgeon-in-chief of the Peter Bent Brigham Hospital.

Dr Moore, who received his medical degree from Harvard Medical School in 1939, has been assistant professor of surgery at Harvard Medical School, assistant surgeon at the Massachusetts General Hospital, consulting surgeon at the Massachusetts Eye and Ear Infirmary and an associate member of the staff of the Palmer Memorial Hospital. He has become widely known for his work in gastrointestinal and thyroid surgery, as well as for his studies with the Office of Scientific Research and Development on the care and treatment of patients with burns. His investigative activities have also included the application of radioactive isotopes to surgical problems. He is a member of the editorial board of the *New England Journal of Medicine*.

The selection of such a young man (the youngest ever named surgeon-in-chief at the Peter Bent Brigham Hospital) for these posts constitutes a great honor and one that is richly deserved. As a successor to John Collins Warren, Maurice Howe Richardson, Harvey Cushing and Elliott Carr Cutler, Dr Moore will hold an enviable academic

position in American surgery, and his status at the Peter Bent Brigham Hospital is one of equal eminence. Those who are familiar with his past achievements are confident that his service will continue the great traditions of his distinguished predecessors. Both Dr Moore and the institutions concerned are to be congratulated on this choice.

## MASSACHUSETTS MEDICAL SOCIETY

### DEATHS

DARLING — Charles B. Darling, M.D., of Waban, died on April 19. He was in his seventy-ninth year.

Dr Darling received his degree from Harvard Medical School in 1894. He served in the United States Army Medical Corps in World War I and was a member of the original staff of the Free Hospital for Women, Brookline.

His widow, two sons and a grand-daughter survive.

McINTIRE — Herbert B. McIntire, M.D., of Cambridge, died on April 21. He was in his ninety-first year.

Dr McIntire received his degree from New York University Medical College in 1882.

His widow and a daughter survive.

ROBBINS — Albert I. Robbins, M.D., of New Haven, Connecticut, died on April 14. He was in his thirty-fourth year.

Dr Robbins received his degree from University of Vermont College of Medicine in 1939. During World War II he served with the United States Army in the Pacific area.

His widow, three sisters and four brothers survive.

## MISCELLANY

### HOSPITALIZATION OF VETERANS

The hospitalization of veterans by the Veterans Administration reached an all-time high of 109,325 on March 1, 1948. This number represents a gain of 1,874 over the previous peak of 107,451 on February 1, and an increase of 37,612 since July, 1945.

The number of veterans awaiting admission has also increased, largely owing to applications from veterans with nonservice-connected disabilities. The Veterans Administration is required to care for veterans with service-connected disabilities and may care for those with nonservice-connected disabilities if beds are available and if they affirm that they cannot afford to pay for treatment elsewhere.

## CORRESPONDENCE

### IN DEFENSE OF WHITE CROSS

To the Editor: In the February 12 issue of the *Journal*, in an article entitled "Principles of the Massachusetts Medical Society," former President Elmer S. Bagnall states:

I remember that in that same committee [Committee of Public Relations] discussion of medical-care plans later developed and that, under the brilliant and aggressive leadership of Dr. James C. McCann, the Blue Shield was conceived and launched. At about the same time the White Cross was born. This was an experiment in medical care sponsored by men who were impatient with such "inadequate" concepts for solution of problems in medical-care distribution as the Blue Shield then seemed to them. I have always thought that these men could have performed a service by reporting on the causes of failure factually and objectively.

As this is the first request from a representative of the Massachusetts Medical Society for information about the White

Cross, it seems appropriate to supply the information to correct some false impressions about the White Cross that are reflected in this quotation from Dr Bagnall's article.

First the White Cross was conceived and born in 1939 while one of the undersigned was president of the Massachusetts Medical Society. Dr McCann was appointed chairman of the committee to conceive the Blue Shield by a successor to the presidency. Thus it is obvious that the White Cross antedated the Blue Shield and was not conceived in impatience or competition with the Blue Shield.

The facts concerning termination of the White Cross may be stated briefly. Early in the winter of 1942 the officers of Medical and Surgical Associates who had assumed the responsibility of providing medical care to the subscribers of the White Cross realized that the majority of the participating family physicians and many of the consultants might enter the armed forces. Medical and Surgical Associates would then be unable to fulfill their obligations to the steadily increasing subscribers to the White Cross. Meetings were therefore held between the officers of the White Cross and Medical and Surgical Associates to meet this contingency. After a month of consultations it was decided that the possibility would actually become a fact since the majority of participating physicians were among the younger active members of the profession. It was therefore decided that Medical and Surgical Associates should avail themselves of the opportunity under the agreement with the White Cross to terminate the contract for medical service on three months' notice. When this decision was announced the subscribers asked that it be reconsidered. Several more meetings were held at which the subscribers sought means of continuing the service during the war. At these meetings the enthusiasm of the subscribers for the service was ample evidence of their satisfaction with it. The subscribers formed an independent organization and begged the Medical and Surgical Associates to continue to take care of the existing subscribers even if the rates should be considerably increased. They said they wished this because they were receiving better medical care than they had received before. With the demands of the war however no solution could be found.

We consider it fair to state that the majority of the participating physicians were interested in this experiment in the provision of complete medical care on a voluntary prepayment basis. Though they had only received approximately thirty cents on the dollar for service rendered they appreciated that more was not to be expected until the scheme had been in operation for several years. In the mean time the burden on any one physician would not be great.

Probably the most important factor in the slow though steady growth in subscribers was the opposition of many members of the medical profession to the service. Though this did not interfere with physicians' willingness to care for patients it did retard group enrollment, so essential for rapid growth and a good distribution of medical risk.

We also wish to record the interest, time and effort that the lay board of the White Cross contributed to the organization and operation of this pilot study. It is interesting that the definitions of specialist and consultant devised for this service have since been accepted and used rather widely. The concept that medical service should be built about the family practitioner supported by adequate consultant and hospital services was satisfactorily applied. In retrospect it seems however, that more organization of the consultant and hospital services is desirable in the interest of quality and economy.

This statement provides the objective thoughts desired by Dr Bagnall. The White Cross was a war casualty. To impute any other hidden cause for termination of the contract by Medical and Surgical Associates is neither objective nor factual.

## BOOK REVIEWS

*Calcific Disease of the Aortic Valve*. By Howard T. Kanner, M.D., and Simon Koletsky, M.D. 8, cloth 107 pp. Philadelphia: J. B. Lippincott Company, 1947. \$5.00.

This volume, which is essentially a statistical monograph analyzes the history and pattern of a condition that has borne various names but for which the authors consider the best to be "calcific disease of the aortic valve." To the complete material derived from this review of the literature they have added the detailed study of 200 cases observed at autopsy. The book serves therefore as a valuable reference work in which both the clinical and the pathological aspects of this disease are submitted to rigorous statistical criticism.

It is pointed out that Mönckeberg first studied the condition isototically and that the most important contributions to its understanding have followed his pioneer effort, even though his emphasis on the arteriosclerotic etiology of the valvular deformity has been supplanted by growing evidence that the cause is almost always rheumatic infection.

The authors consider the factors of age, sex and race, pointing out that calcific disease of the aortic valve is largely a disease of later life, that its preponderance in males is less than has been thought (1.6:1.0) and that it is infrequent in the Negro. The heart is generally large in fact almost as large as that in syphilitic aortic insufficiency.

The pathological findings with excellent illustrations are presented in detail, as is the correlation of the aortic lesion with the stigmata of rheumatic involvement elsewhere in the heart.

The clinical examination is also carefully analyzed with consideration of angina pectoris, syncope, character of the pulse, murmurs, thrill, blood pressure and electrocardiogram. In only about half the cases in their series in which electrocardiograms were recorded was there left axis deviation. The value of visualization of the calcific aortic valve area by x-ray examination is emphasized.

Sudden and unexpected death occurred fairly often but most patients died of congestive failure.

Of 190 patients in whom a clinical diagnosis might have been made it was offered in only 48. Attention to the information and suggestions in this book should improve this diagnostic figure.

*Nutritional Disorders of the Nervous System*. By John D. Spillane, M.D. (Wales) M.R.C.P. (London). With a foreword by George Riddoch, M.D. F.R.C.P. 8, cloth, 280 pp. with 103 illustrations. Baltimore: The Williams and Wilkins Company, 1947. \$5.00.

During World War II, owing to the long confinement of prisoners of war and persons in the concentration camps there was an unusual chance to investigate nutritional disorders of the nervous system. The author studied patients with this type of disorder particularly English prisoners of war in the Far East and civilians confined in Hong Kong. In addition to his personal observations he reviewed the reports of other physicians with similar experiences in the Philippines and elsewhere. Detailed case histories are given with excellent illustrations both by photographs and by diagrams. The book contains references to the pertinent literature. This study is an outstanding one far exceeding anything of its kind previously published.

*Handbook of Psychiatry*. By Winfred Overholser, M.D., Sc.D., and Winifred V. Richmond, A.M. Ph.D. 8, cloth 252 pp. Philadelphia: J. B. Lippincott Company, 1947. \$4.00.

The authors have succeeded in setting forth modern psychiatric concepts in simple, nontechnical language. The volume has been prepared for intelligent lay persons and for relatives of mental patients, but it will probably be in the library of most specialists in psychiatry.

The material in the text, which has been presented in an undramatic, conservative manner is easily read and well organized and written with the exception of a few typographic errors. It may fail to reach the general public as the authors hoped because of its resemblance to a standard textbook of psychiatry.

Treatment of mental disorders is discussed only in a general way, self-treatment is discouraged. There is an excellent reading list at the end of each of the seventeen chapters.

The chapters on "alcohol and its role in the psychoses," "crime and mental disorder" and "psychiatric conditions in childhood," to mention only three, contain many facts and explanations that should be more generally known and understood by the public. The purpose of the authors to educate the average man and woman is indeed praiseworthy, the results may not be encouraging because the man on the street prefers picture magazines.

The clarity of the language is a tribute to the psychiatrist and the psychologist who collaborated in writing it. College students, nurses and other professional groups can read this handbook with ease and profit.

*What is Psychology? A basic survey* By Werner Wolff, Ph D. 8°, cloth, 410 pp., with 39 illustrations. New York: Grune and Stratton, 1947. \$4.00.

The author of this volume hopes to arouse a healthy skepticism of the various theories and methods in psychology and to create an interchange among collegiate classes of experiments in "depth psychology." He would have done better with an epistemologic discourse or an experimental presentation, rather than the pseudoexperimental approach taken. It appears that too much ground has been covered in too short a space to do justice to the author's points of view. The result is somewhat of a hodgepodge of experimental material and hypothetical musings, which are used sometimes to substantiate and sometimes to refute the point at issue. As a text for use with the author's own classes it may serve its purpose, its value as provocative material in other areas is questionable.

*Trichomonas Vaginalis and Trichomoniasis* By Ray E. Trussell, M.D. With an introduction by E. D. Plass, M.D. 8°, cloth, 277 pp., with 19 illustrations and 16 tables. Springfield, Illinois: Charles C. Thomas, 1947. \$6.00.

It was in 1836 that Donne discovered and named the protozoan parasite *Trichomonas vaginalis* but not until 1916 that Hoehe first described its pathogenic properties. During the past thirty years there has accumulated, on the subject of trichomoniasis and its treatment, an enormous literature that the present monograph aims to summarize and evaluate. The author has also done extensive biologic, experimental and laboratory research, and was the first to obtain the organism in pure culture. He describes in detail its history, morphology, chemical, cultural and staining characteristics, and discusses its pathogenicity and the clinical phenomena of *Trichomonas* infections. Finally he investigates its treatment and presents an alphabetical index and discussion of 185 chemical and other agents that have been utilized in efforts to eradicate it. It is noteworthy that, of the antibiotics, only tyrothricin and tyrocidin have shown any effect whatever.

The text of this authoritative work is adequately illustrated with 19 figures and 16 tables and has an exhaustive bibliography of 1586 references. One appendix summarizes the taxonomic relation of *Trichomonas* to other protozoa, and another presents a parasite-host list of 167 known species. There is an admirable introduction by Dr. E. D. Plass, professor of obstetrics and gynecology in the State University of Iowa, in whose laboratories and libraries the research was done.

## BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*Diseases of the Joints and Rheumatism* By Kenneth Stone, D.M. (Oxon), M.R.C.P., physician, B.R.C.S. Clinic for Rheumatism and Physical Treatment, Kensington. 8°, cloth, 362 pp., with 58 illustrations. New York: Grune and Stratton, 1947. \$6.50.

*Fatigue and Impairment in Man* By S. Howard Bartley, Ph.D., professor of research in the visual sciences, Dartmouth Eye Institute, Dartmouth Medical School, and Eloise Chute, M.A., research associate in the visual sciences, Dartmouth Eye Institute, Dartmouth Medical School. With a foreword by A. C. Ivy, Ph.D., M.D., vice-president, Chicago Professional Colleges, University of Illinois. First edition. 8°, cloth, 429 pp. New York: McGraw-Hill Book Company, Incorporated, 1947. \$5.50.

*Unipolar Lead Electrocardiography Including standard leads, unipolar extremity leads and multiple unipolar precordial leads* By Emanuel Goldberger, M.D., adjunct physician, Montefiore Hospital, New York City, cardiographer and associate physician, Lincoln Hospital, New York City, and clinical lecturer in medicine, Columbia University, Faculty of Medicine. 8°, cloth, 182 pp., with 88 illustrations. Philadelphia: Lea and Febiger, 1947. \$4.00.

*Radium Dosage The Manchester system* Edited by W. J. Meredith, M.Sc., F.Inst.P., Christie Hospital and Holt Radium Institute, Manchester. 8°, cloth, 124 pp., with 38 illustrations, 4 plates and 27 tables. Baltimore: Williams and Wilkins Company, 1947. \$4.50.

## WHITHER THE PEGASUS OF PUBLIC HEALTH?\*

HAVEN EMERSON, M.D.†

NEW YORK CITY

TWO preoccupations require the attention of anyone responding to the call for such a lecture as the present opportunity demands. Regard for the intellectual and personal contributions of one's predecessors in this thirty-year series will create a proper humility of spirit. A hope to meet the long-ago wishes of the founder of the lecture-ship should provide the courage or perhaps explain the recklessness of one who presumes that he has a message worthy of such an academic and professional audience

\* \* \*

Whereas the original Pegasus of Greek legend seems to have been the only offspring of Neptune and the golden-haired Medusa whom Minerva so cruelly punished for the sea god's infatuation by turning her locks into serpents, ours is the winged horse on which Bellerophon rode when he slew the fabulous vanbodied Chimaera that spouted fire

The medical officer of health is modern democracy's Bellerophon, the son of Glaucus and grandson of Sisyphus, who advances upon all enemies of his fellow men on the wings of science. He is mounted on such a steed of speed and energy as will strike poetry out of the dull earth of human misery even as Pegasus of yore brought forth the fountain of the Muses, the Hippocrene on Mount Helicon, by a stamp of his hoof upon the arid rock.

Although the life history of our chosen field of scientific endeavor for society's sake is but a brief moment in the story of man, and the names of the originators of the public-health movement are few and easily recalled, I venture, instead of playing the role of thumb-nail historian, to quote two principles, or expressions of deep reasoning that seem to me to reach the essence of our problems of today and to add a sense of maturity and solidity to what has been so far a fairly successful philosophy and performance

\* \* \*

Among the papers of Abraham Lincoln revealed in July, 1947, for the first time to scholars and to students of our greatest citizen, our wisest and most beloved President, a fragment in his handwriting found in his worn carpetbag may well be remembered and taken permanently to heart by all who either share in the privilege of our suffrage or play a part as employees of civil government at any level of jurisdiction. Lincoln wrote as follows

The legitimate object of government is to do for a community of people whatever they need to have done but cannot do at all or cannot do as well for themselves in their separate and individual capacities. In all that the people can do as well for themselves the government ought not to interfere.

Perhaps we should expend less pomp and circumstance upon a mere centennial of medical organization in our country or on the seventy-five years of the American Public Health Association's life and devote more celebration to this, the six hundred and fifty-sixth year of Switzerland's independence as an autonomous representative government of a free people. The first three Cantons in 1291 entered into a perpetual pact to safeguard their system of local self-government in opposition to the officials set up by the Hapsburgs. There are threats today against the integrity and independence of our local governments by the successors in spirit of those officials

What treasures have been revealed to us by explorers into the secrets of nature had been but barren gifts if we had not held precious the principles of democratic freedom as a framework of our society within which the practical blossoming and fruiting of the sciences has been continuous and abundant. This has been obstructed only by the reminders of superstition, tradition and ignorance among us, and by the inertia and small-mindedness of a few here and there to whom the reins of government and the appropriation of tax money have been unsuitably entrusted. It is the supplementing of individual resourcefulness, initiative and responsibility by the collective authority, prestige and tax

\*The Carter Lecture on Preventive Medicine delivered at Boston November 24, 1947

†Visiting professor of public health practice, Columbia University College of Physicians and Surgeons; member, Board of Health, City of New York.

public health is necessarily set by the level of common understanding of the causes and effects, the processes and products of human physiology in terms of personal survival and social conduct. Neither virtue nor health is a necessary product of information, nor is vice a certain sequel to ignorance, but knowledge helps man escape the pitfalls of ignorance and avoid superstition and the inertia of tradition.

A valuable resource gradually being made available for small towns as well as some large cities is the health museum for visual education, a sort of temple of health, on a par of dignity, popular usefulness and aid to culture with the public library and the art museum.

Whatever is not done by the institutions devoted entirely to education to teach good sense about health from nursery classes through the university professional and graduate schools must be attempted, when of vital importance, by departments of health, if only temporarily until the needed information can be incorporated by systematic presentation in schools and colleges. The weakest phase, if not actually nonexistent for the most part, of health information through public-health agencies is that regarding the use of habit-forming drugs and self-medication with potent and hazardous sedatives, in particular the world's most recklessly used depressant, ethyl alcohol, and for the moment in this country the barbiturates. The damage to the quality of social relations, to the conduct of persons and the invariable inferiority of performance of bodily and mental functions resulting from the prevalent use of alcohol are sufficient reasons for dealing as frankly with its properties as we do with the values of cows' milk. Health officers do not dare to declare the full truth of the baleful effects of alcoholic beverages, as widely used, upon human health.

There is, besides the considerable number of opportunities for enlargement of the scope and refinement in the methods of fulfilling the existing accepted basic functions of a local health department, at least one serious defect in the present preparation of the various professional participants on its staff. We of the public-health professions lack an orderly and approved provision for field training during and after completion of the courses offered in schools of public health to physicians, sanitary engineers, public-health nurses, educators and others. State and local health departments require in-service training courses and practical field experience for each person added to their staffs. No graduate of a school of public health should be thought of as prepared for a position in a health department until he has had at least six months of supervised field training in a local health service with good standards of performance and personnel assigned to the special duty of trainee supervision.

That such training centers will be provided in the near future appears to be certain, and it may be noted here that the urgency of the need for these, and the quite unsatisfactory conditions for local rural or extra-city field training, is nowhere greater than in the New England states, and yet in these very states at present the conditions of local rural health services are not favorable for the development of such training areas.

\* \* \*

And now I am at your mercy, having ventured to glimpse the future of public health in our time, rather as I believe it should and may develop than as some of the current trends of social promotion and political opportunism would prefer it.

Frankly, I believe it would set back the hands of time, confuse public thinking, lower the respect for "state preventive medicine" and allow people to believe that more abundant care of the sick would materially improve the public health, if hospitals and other institutions for the sick were administratively included within public-health services. Regarding the following extract from a recent report on intergovernment relations in a typical agricultural county of southern Minnesota, it may be well to understand in Massachusetts also certain facts and opinions against which we must project the future administration of local public-health services.

The town meeting, city hall, and county court house are no longer the seat of local government. Alongside them and in their place have sprung up a large number of government agencies operating under a line of authority and responsibility that travels the long and circuitous route from the electorate to Washington and back to the locality. We may note that with this the cost has risen and the tax dollar is worn thin by its travels. The weakness of the existing system of public health administration is not due to lack of organization of any single unit or agency in the field of public health, but rather, to the disconnected operation of many agencies engaged in similar activities.

State and federal funds have been slow in making their way into the community. Nearly all federal grants and state appropriations are used directly to finance the activities of state administrative agencies, a very small part is passed on to local units to support programs of their own.

In Blue Earth County of Minnesota with about 40,000 population a careful study revealed 155 units of local government charged with many similar and oft-times over-lapping functions, some 105 state agencies and 38 federal agencies with offices in the county, a total of 298 units and agencies of government serving the people of this county, exclusive of the over-all ministrations of the state and federal governments.

Of our 155,000 units of government in the United States, we have about 150,000 too many.

Admitting that we have too many governmental units—one for every 850 people and every 19 square miles—it is highly improbable that we shall see any marked decrease through compulsory methods for many years to come. It is more likely that a desirable reduction in the number of governmental units will come only after practical demonstration of cooperative action along functional lines.

Let me close by briefly putting before you the structure of public health as I see it, a possible and

certainly desirable function of civil government. First in time and importance will be the 1200 or so units of local health administration (instead of the present 18,000 health departments), from the least of perhaps no more than 30,000 persons, and preferably not less than 50,000, to the largest and one of the oldest, the five-county unit of the City of New York.

These will be the chief instrument of public health in the United States, with the consultative, advisory, standardizing and probably financial backing of the state departments of health and the long-awaited single federal health authority, the last also giving invaluable support through financial and technical aid and the benefit of its interstate and national functions. Federal aid will be based on evidence of a competent state plan for total coverage by local services whose functions, methods and personnel have been officially declared, and then funds will be available only to units recognized as too economically disadvantaged to meet the cost of their health department from local and state tax resources alone.

With such a nation-wide administrative structure the basic functions will first be performed with increasing approach to competence before the diversion of dollars and personnel to other and less productive even though temporarily popular activities take place. We have the authority, the technical knowledge, the practical "know-how" to justify a future of higher goals, to make an en-

during success of the trial marriage of medicine, or the art of human biology, and representative civil government on our familiar pattern of a democracy. We need better methods, more critical self-analysis, the use of administrative epidemiology, as well as better trained personnel and more liberal conditions of their employment.

\* \* \*

For all, the health benefits now available to part of our people shall follow. And when it is all said and done we find in the few lines from Shakespeare that it need not have taken so many words of mine to relate or so many of your precious collective minutes to listen.

"If to do were as easy as to know what were well to do, chapels had been churches and poor men's cottages prince's palaces."

And without more to-do let us mount our Pegasus of today, and as the Bellerophons of modern democracy lead our fellow men, women, and children to heights of health that can be seen at a distance, but not out of reach for those who accept the hazards of leadership.

Let us who are concerned professionally with the career of public health concentrate the resources of the sciences and of civil government upon the prevention of disease, relying upon the age-old guild of practitioners of the healing art to provide the skills and humane consideration due the sick and suffering.

600 West 158th Street

## RECONSTRUCTION OF THE BURNED HAND\*

RADFORD C. TANZER, M.D.†

HANOVER, NEW HAMPSHIRE

**R**ECONSTRUCTION of the burned hand starts at the time of the initial dressing. Intelligent treatment during the first month will effectively prepare the hand for later restorative procedures, whereas misguided handling may thwart all efforts to bring back full function.

### EARLY TREATMENT

It is generally agreed that the immediate local treatment of a burned hand includes a minimal amount of debridement confined at most to the gentle removal of vesiculated epidermis and the application of a firm, even pressure dressing. The fingers should be packed individually, and the entire hand encased in a bulky, fluffed-gauze dressing retained by a snug elastic bandage. The position of the hand within the pack is important. Fingers

should be spread, and all joints fixed in moderate flexion, a position easily obtained by having the hand grasp a large gauze ball. This also brings the thumb well away from the index finger into a position of opposition. The wrist is supported by a light dorsal plaster splint in slight dorsiflexion. In other words, the hand is immobilized in a position of function where any permanent limitation of motion will prove least deleterious.

Cope and his associates<sup>1</sup> have called attention to the manifest advantages of the immediate or early excision of severely burned areas and replacement by free skin grafts. Although this method has a place in the treatment of the burned hand, one must appreciate the fact that the anatomic features of the hand, with its dearth of subcutaneous tissue, necessitate a dissection uncomfortably close to important structures such as the extensor tendons and the aponeuroses of the fingers. Unless a graft can be applied accurately and made to adhere com-

\*Presented at the annual meeting of the New England Surgical Society, Providence, Rhode Island, October 3, 1947.

†Assistant professor of surgery, Dartmouth Medical School; member surgical staff, Hitchcock Clinic.

pletely, the result may be damaging to function, hence the method should probably be reserved for

FIGURE 1 Photograph Showing Spotty Depigmentation of the Skin after a Severe Burn

cases of localized burn in which the possibility of any significant loss of graft is slight

If a paste of pyruvic acid and starch<sup>2</sup> is used to hasten the extrusion of slough, one can still retain the position of function when dressings are applied

First consideration should be given to mobilizing the hand as early as possible to minimize edema and to maintain joint action. Therefore, active and passive exercises should be started even before the grafts are fully stabilized, the attendant watching carefully for bleb formation and splinting any such area until the tendency to loosen has passed. New grafts and newly formed skin must be carefully protected. The patient can do this consciously during the waking hours, but at night protective dressings should be reapplied to guard against trauma during sleep. This is the best time to correct incipient contractures. Proper positioning of the digits on a night splint, with gentle elastic traction at strategic points, should maintain a functional position throughout this phase of stabilization of integument. Once this state is reached one can start a program of occupational therapy and await softening of scar and improved nutrition of the hand before considering a more permanent type of replacement. In many cases the primary graft may prove quite satisfactory, and no further resurfacing will be needed.

#### LATER RECONSTRUCTION

Skin presents a curious variation of response to thermal injury. One type occasionally seen is the

FIGURE 2 Preoperative (A) and Postoperative (B) Photographs of Contracting Scar Replaced by a Near-Full-Thickness Graft from the Abdomen  
Note the broken line crossing the dorsum of the wrist

This likewise applies to the phase of moist dressings that may be used to prepare the wound for grafting

Any granulating areas should be resurfaced as soon as the nutrition of the wound permits. Exuberant granulations are shaved down and covered with split-thickness skin grafts of 0012 to 0018 inches. It is desirable to excise intervening areas of spotty epithelium, but attempts to carry out a complete resurfacing of the dorsum of the hand and fingers, including a dissection down to the investing membranes of the tendons, had best be deferred to a later time.<sup>3</sup>

spotty depigmentation of the dorsum (Fig 1), which is not necessarily associated with keloid or contracture, but which in itself may offer sufficient reason for replacement. One should be sure that the process has become stationary, however, since pigmentation often returns in the course of time.

Hypertrophic keloid is a common manifestation of burned skin. It is desirable to wait until the erythematous phase has subsided before proceeding with replacement unless contractures demand early attention. In equivocal cases it is well to temporize

since even heavily developed keloids will soften within the course of months

The principal indication for resurfacing is the presence of constricting or unstable scar. A hand

the abdominal wall. Hence for expediency the split-thickness skin graft,<sup>4</sup> taken either free hand or with a dermatome, is usually employed. This gives adequate stability, does not contract unduly

FIGURE 3 Photographs Showing Constricting Keloidal Scars of the Dorsum of the Hands (A) and Replacement by Split Thickness Grafts (B)

Note position of line of juncture of grafts at base of right thumb (C)

enclosed in the vise-like grip of a burn scar is lacking proper nourishment as well as suffering from the mechanical effects of the tightness. A scar that tends to form superficial ulcerations at the slightest trauma is a severe economic handicap.

A most satisfactory type of resurfacing employs the near-full-thickness skin graft, which is dissected

and in most cases furnishes an inconspicuous color tone.

At the Hitchcock Clinic dorsal resurfacing procedures are carried out under a tourniquet. The scar is elevated at its natural cleavage plane, and the dissection carried to the line dividing volar and dorsal surfaces of the hand and of any affected

FIGURE 4 Photographs Showing Severe Contractures and Imbedding of the Volar Aspects of All the Fingers of the Right Hand in Scar (A) and Release of Contractures by Free Grafts of the Entire Volar Surface and Part of the Dorsum (B)

The useless little finger has been amputated

off the abdominal wall by scalpel and the defect closed by undermining after the remaining thin sheet of dermis has been removed (Fig 2A and B). Although this gives excellent stability with a minimum of shrinkage, the method requires both a great deal of time and an extensive procedure on

digits. Only the portions of the digits that show tightness or instability are denuded. The tourniquet is then released, and hemostasis effected.

Split-thickness skin grafts approximately 0.022 inch thick are removed with a dermatome. For complete coverage of the dorsum of a hand one

and a half drums are removed. The graft comprising one full drum is used to cover the fingers and their metacarpals. The half-sized graft will cover the thumb and the triangle at its base. All suture lines are placed so as to avoid contractures

FIGURE 5 *Complex Contractures of the Fingers Involving the Joint Capsules*  
*Replacement of scar by free grafts has not overcome the deformity*

(Fig 3) Lines extending across expanding and contracting portions of joints are avoided if possible. When such a line is necessary it is broken into oblique components by means of a dart (Fig 2B). The grafts are trimmed to fit the defect accurately

guard against excessively tight bandaging, which has been known to cause ischemic contracture.

In cases of more extensive damage, particularly in cases in which digits are involved, the base may be unsuitable for free grafting, or the loss of tendons and joint capsules may necessitate further reconstructive work. Such cases necessitate the more protracted method of resurfacing by means of direct pedicle flaps using skin and underlying fat from the abdominal wall or from the opposite arm.

Burns of the volar surface of the hand, although less frequent, are usually associated with severe damage to the hand generally and present baffling problems in restoration. If flexor tendon sheaths are preserved one may find it possible to release contractures by free grafts (Fig 4), otherwise it may be necessary to use a tubed pedicle flap through which corrective procedures on the tendons and joints may be carried out later.

Contractures of the interdigital webs are an almost constant finding in significant burns of the dorsum of the hand. When a free graft is applied dorsally this web may be broken by carrying a point of the graft well down to the volar aspect.

Residual joint contractures may be produced in various ways. Lack of splinting will allow severely burned hands to assume grotesque positions. On the other hand improper splinting, particularly immobilization on a flat splint, may result in complex contractures of the digits and adduction contracture of the thumb.

A common type is extension contracture of the metacarpophalangeal joints due to tightening of skin

FIGURE 6 *Two Types of Splint (A and B) Used to Produce Flexion of the Metacarpophalangeal Joints, Extension of the Proximal Phalangeal Joints and Abduction and Opposition of the Thumb*

and are sutured to the wound margins without overlapping. Firm, even pressure is applied by careful packing, and the hand immobilized in a functional position as described above. Although the dressing should be applied snugly, one should

and shortening of extensor tendons. The almost invariable concomitant of this contracture is a flexion contracture of the proximal phalangeal joints (Fig 5). If skin replacement fails to correct this deformity one should use a splint of the type repre-

presented in Figure 6A and B, which, while permitting active exercise, maintains elastic traction to straighten the finger contractures and to bring the thumb away from the index finger and into opposition.<sup>8</sup> If corrective splinting fails capsulectomy may improve position of the metacarpophalangeal joints and if this is ineffective, fusion is indicated. Occasionally it has proved advantageous to perform a capsulectomy of the metacarpophalangeal joints at

splinting of the thumb in a position of function, but if integumentary loss has been significant a free graft will be needed to permit adequate abduction. If the contracture has been existent for a long period, simple replacement of skin will not correct the deformity inasmuch as the adductor muscles will have become shortened and fibrotic. This condition can be improved if one detaches the adductors from their insertions at the base of the

FIGURE 7 Photographs Showing Keloidal Scarring of the Dorsums of Both Hands with Complex Contracture of the Right Little Finger (A) and Correction by Amputation of the Little Finger and Part of its Metacarpal (B) Skin of the Amputated Finger Being Used to Release Extension Contracture of the Ring Finger

The dorsum of the left hand has been resurfaced by a free graft.

the time of resurfacing, as described by Shaw and Payne,<sup>8</sup> which permits proper positioning of the fingers when the grafts are applied.

The little finger is particularly prone to develop complex contracture. If the deformity is severe I have occasionally amputated the finger, together with part of the fifth metacarpal bone, thereby giving the patient a stable, well functioning hand of reasonably satisfactory appearance and avoiding a long program of reconstruction that at best offers only partial function (Fig 7).

Another frequently noted deformity is a flexion contracture of the metacarpophalangeal joints. This often signifies that the extensor tendon and the hood have been destroyed or split, allowing the two halves to slide off the prominence of the knuckle into the intermetacarpal fossae. The initial correction should consist of an extension splint to the proximal phalanges to overcome the unopposed action of the long and intrinsic flexors, and then of replacement or resurfacing of the damaged extensor tendon and hood mechanism.

Flattening of the thumb with adduction contracture may be minimized by early and effective

first phalanx and reattaches them more proximally on the first metacarpal, deepening the web and permitting the thumb to fall into a more abducted position.

#### SUMMARY

Restoration of a burned hand starts with initial immobilization in a functional position.

Early replacement of constricting or unstable scars is most important in restoring proper nutrition and avoiding contractures.

Proper elastic splinting should be employed not only in the correction of contractures but also, more assiduously, in the prevention of contractures.

# PHEOCHROMOCYTOMAS COEXISTING IN ADRENAL GLAND AND RETROPERITONEAL SPACE, WITH SUSTAINED HYPERTENSION\*

## Report of a Case with Surgical Cure

EMIL J. GANEM, M.D.,† AND GEORGE F. CAHILL, M.D.‡

NEW YORK CITY

**P**HEOCHROMOCYTOMA as a cause of hypertension is being more frequently recognized than it was a decade ago. There are several reasons for this.

In recent years physicians have become increasingly familiar with the variegated symptom-complex produced by these tumors.

The recent trend for complete diagnostic survey in patients with high blood pressure leads occasionally to the discovery of an unsuspected adrenal tumor.

Emphasis on the part of many observers that these tumors may produce persistent unremitting hypertension clinically indistinguishable from essential hypertension has led to a greater suspicion of their presence in the study of hypertensive patients.

Improved technics in the diagnosis of early enlargements of the adrenal gland, such as intravenous pyelography and perirenal insufflation of air and other gases, have helped immeasurably in the localization of tumors too small to be demonstrated by other nonsurgical means.

Thoracolumbar sympathectomy, which brings the adrenal gland into view on the operating table, is being done with increasing frequency for the treatment of hypertensive disease.

Complete cure of the syndrome, with return of the blood pressure to normal, is not an infrequent sequel to surgical extirpation of the tumor. The operative mortality in these cases has recently been strikingly reduced as a result of increasing knowledge regarding epinephrine shock and its control by appropriate administration of adrenalin and the adrenal cortical extracts when indicated.

Multiple pheochromocytomas occur rarely. Of the surgically cured cases of pheochromocytoma recently summarized by MacKeith,<sup>1</sup> all were solitary. The following case report is thought to be of interest because it represents the first recorded case of multiple pheochromocytomas surgically cured.

## CASE REPORT

A 12-year-old girl of Italian extraction was admitted to the hospital in September, 1943, because of excessive perspiration and increased appetite with failure to gain weight. The illness had begun 2 years before admission, when she first noticed a tendency to sweat profusely. She began to be intolerant of heat. Her appetite became excessive, and yet she had gained no weight, and shortly before admission she had begun to lose weight. She noticed excessive thirst and drank large quantities of water. She complained of easy fatigability and of palpitations, stating that the heart often beat fast, even without exercise. Occasionally, she sensed numbness and tingling in the hands. Two determinations of the basal metabolic rate before admission had been reported as +50 per cent and +30 per cent.

The past and family histories were noncontributory. Physical examination disclosed an undernourished, apprehensive, emotionally unstable girl. The skeletal development was good. The skin was always warm and moist. The eyes showed no evidence of exophthalmos, and the eye grounds were normal. The eye signs of thyrotoxicosis were conspicuously absent. The thyroid gland was not palpably enlarged. The chest was clear. The heart was not enlarged, and the rhythm was regular. No murmurs could be heard. The liver edge was felt two fingerbreadths below the right costal margin. No abdominal masses could be felt. Application of pressure over the abdomen failed to influence the level of the blood pressure. The reflexes were physiologic.

The pulse consistently averaged 120, and the blood pressure 180/120, the hypertension being unremitting and not paroxysmal.

Examination of the blood revealed a normal red-cell count, hemoglobin, white-cell count and differential count. Urinalysis showed a specific gravity of 1.024, a slight trace of albumin, no glucose and an occasional white cell in the sediment. The glucose tolerance test gave a diabetic type of curve. The fasting blood sugar was 88 mg., and the non-protein nitrogen 34.6 mg. per 100 cc. The blood iodine level was 4.8 microgm. per 100 cc. (normal average 6.2 microgm.). Several determinations of the basal metabolic rate varied from +51 to +67.6 per cent. The serum cholesterol was 215 mg. per 100 cc. An electrocardiogram showed sinus tachycardia. X-ray films of the skull and the chest were normal. A plain film of the abdomen disclosed a tiny area of calcific density in the region of the left suprarenal shadow.

The patient was observed repeatedly for the next 9 months, during which the physical findings remained unchanged except that by June, 1944, the blood pressure had risen to 200/150 and a soft, blowing systolic murmur could be heard over the apex. The eye grounds showed blurring of the disk margins, with papilledema. The arteries were markedly narrowed, and the veins showed nicking at the arteriovenous crossings. Several fluffy-white exudates and a flame-shaped hemorrhage could be seen. These signs of hypertensive retinopathy progressed rapidly while the patient was under observation.

A trial with Lugol's solution failed to influence the clinical state.

Intravenous pyelograms were normal. Bilateral perirenal insufflation of air was carried out, and considerable enlargement of the left adrenal gland was visualized on the x-ray film (Fig. 1).

A diagnosis of tumor of the left adrenal gland, probably intramedullary pheochromocytoma, was made, and through an extraperitoneal lumbar approach, the left adrenal gland was explored and found to contain, in its midportion, an encap-

\*From the Department of Urology, Columbia-Presbyterian Medical Center.

enlarged globular tumor 2.5 cm in diameter. The blood vessels leading to it were found to be dilated. Manipulation of the tumor while the patient was under anesthesia caused a rise in the blood pressure from 170/120 to 200/160 and in the pulse from 130 to 170 but with removal of the tumor the blood pressure fell to 60/30, requiring intravenous adrenalin intramuscular adrenalin-in-oil and 10 cc. of adrenal cortical extract (eschatin) subcutaneously. It was thought that a mass distinct from the adrenal gland could be felt but in view of the patient's condition, further exploration and further surgical exposure seemed unduly hazardous and were not carried out.

The tumor weighed 6 gm. It was yellow, soft and lobulated containing two small, triangular shaped, red areas suggestive of infarction. Microscopically it was composed of rounded masses of cells, with large nuclei containing fine distinct granules and fine threads of chromatin which could be seen as greenish brown granules in the cytoplasm when stained with Schmorl's stain (Fig. 2). The capsule consisted of a thick fibrous layer. The tumor showed no inclination to pass this barrier and was considered a cytologically benign pheochromocytoma. Treatment with ferric chloride solution yielded a deep olive-green color indicating the presence of adrenalin or an adrenalin like substance in the tumor. A qualitative test of the tumor was made for adrenalin by Dr. C. Harrison Snyder, Jr. An acid aqueous extract

still present. This impression was given support by the suspicion of a mass that, at the time of the first operation, had been thought to be present and also by the benzodioxane studies.

Eight weeks after the first operation, the abdomen was explored, and in the left retroperitoneal space, a spherical tumor, 4 cm in diameter, could be felt and was found lying medial and cephalad to the left adrenal gland and quite distinct from it. This was removed through a left subcostal

FIGURE 2. Photomicrograph Showing the Histopathology of the Benign Intramedullary Pheochromocytoma

Note the presence of large, irregular cells with deep-staining granular cytoplasm and eccentric nuclei. The granules appear greenish in Schmorl's stain.

FIGURE 1. Plain Film of the Adrenal Glands Taken after Bilateral Perinephric Air Insufflation.

Marked triangular enlargement of the left adrenal gland due to the presence of the intramedullary pheochromocytoma is seen. The right adrenal gland is not enlarged. Note that the position and axis of the left kidney are not remarkable.

of the tumor was prepared and a few drops placed in the conjunctival sac of a rabbit upon which a unilateral cervical sympathectomy had previously been done. The eye on the normal side was not affected but the denervated eye dilated maximally even with high dilutions of the extract. This test, although not quantitative is considered highly specific for adrenalin.

After the removal of the intra adrenal pheochromocytoma the blood pressure fell to a level lower than that before operation, and symptomatically the patient experienced relief from the excessive sweating. However the blood pressure was still pathologically high averaging 160/144. It was considered likely that there was some adrenalin-producing tissue

oblique transperitoneal incision. It probably originated in the first or second lumbar sympathetic ganglion.

The tumor was encapsulated rubbery in consistence and yellow green. It had essentially the same architectural pattern as the original intra-adrenal tumor. Schmorl's stain again showed large amounts of chromaffin material.

Postoperatively the blood pressure fell to 138/100. Six months after operation the blood pressure had fallen to 114/54. The patient was completely asymptomatic. The excessive perspiration and ravenous appetite had disappeared. She had acquired a healthy respect for the cold and no longer experienced any palpitation or numbness and tingling in the extremities.

One and a half years after the second operation she was in vigorous health having gained 28 pounds in weight. The blood pressure was 116/78, the basal metabolic rate was +5 per cent, visual acuity was 20/20 and there was complete disappearance of papilledema, hemorrhages and exudates. She was apparently completely normal.

#### CLINICAL ASPECTS

Many adequate descriptions of the syndrome of paroxysmal hypertension due to tumors of the adrenal medulla have been given in the literature and need not be reviewed. Although the disease is thought to present symptoms of paroxysmal attacks of hypertension, with copious perspiration, tachycardia, palpitation, headache, numbness and tingling in the extremities, there has been a tendency on the part of recent authors to emphasize the statement that the hypertension may be well sustained and need not be paroxysmal. In this way, the distinction between this disease and malignant hypertension may present real diagnostic difficulties, as pointed out by Palmer and Castleman.<sup>1</sup> In other words, the discharge of adrenalin or some adrenalin-like pressor substance from the tumor need not be paroxysmal, but may be continuous. Indeed,

Howard and Barker<sup>3</sup> concluded from their study of 18 cases that persistent hypertension is too common in this disease to be ignored as part of the syndrome. Quinby<sup>4</sup> has also reported persistent hypertension in pheochromocytoma.

The hypermetabolism noted in the case presented above has been previously described. McCullagh and Engel,<sup>5</sup> of Cleveland, reported 2 cases with high basal metabolic rates. The differential diagnosis between pheochromocytoma and hyperthyroidism was facilitated in the case reported above by a normal blood iodine level. The poor response to Lugol's solution was also considered strong evidence against hyperthyroidism.

The differential diagnosis between psychoneurosis and hysteria on the one hand and pheochromocytoma on the other may present some difficulties, as pointed out by Van Epps et al.<sup>6</sup> Peculiar sensations, such as choking and a full feeling in the neck, precordial and substernal distress, are symptoms difficult to evaluate. The numbness and tingling of the extremities, with blanching on one occasion, suggested the possibility of an angiospastic condition such as Raynaud's disease.

A remarkable case of hypertension associated with diabetes was reported by Duncan, Semans and Howard.<sup>7</sup> After removal of the pheochromocytoma the blood pressure fell to normal, and the diabetes mellitus completely disappeared.

It is significant that intravenous pyelograms failed to disclose the presence of a suprarenal tumor. In 11 of the 18 cases studied by Howard and Barker,<sup>3</sup> the adrenal tumors were diagnosed by pyelography. If perirenal insufflation of air had not been resorted to, the intra-adrenal tumor in the case reported above would have been missed, since pyelographic demonstration of displacement of the kidney and alteration in its axis was insufficient to suggest the presence of a tumor in the left suprarenal space. Cahill<sup>8-10</sup> has stressed the importance of perirenal air insufflation in the localization of small enlargements of the adrenal gland that can be preoperatively identified in no other way.

Other laboratory determinations have been found to show some departure from normal. The serum potassium has been found elevated, as has the urea clearance. The explanation given by McCullagh and Engel<sup>5</sup> for the increased urea clearance is the "rapid flow of blood through the tissues." The administration of adrenalin to a normal subject produces a decrease in renal blood flow, an unchanged rate of glomerular filtration and a marked increase in filtration fraction—changes indicative of afferent glomerular arteriolar constriction.

The peripheral blood flow is decreased during hyperadrenalinemia. The skin temperature is reduced, and the peripheral resistance is increased. In a patient with pheochromocytoma Evans and Stewart<sup>11</sup> observed these changes, which were reversed after removal of the tumor. These authors

explain the attacks of perspiration as resulting not from direct autonomic sympathetic stimulation of the sweat glands but as a response of the body to a state of increased heat production (as produced by the hypermetabolism and noted in the elevated temperature) combined with decreased peripheral blood flow. Profuse perspiration leads to cooling by evaporation, the excess heat being thus dissipated.

By 1940 only 11 cases of extra-adrenal pheochromocytoma had been reported, 9 of these were tumors of Zuckerkandl's organ, 1 was in a retroperitoneal ganglion near the origin of the superior mesenteric artery, and 1 was intrathoracic, occurring in the right pleural cavity paravertebrally at the level of the sixth intercostal space. In 1940 Phillips<sup>12</sup> reported a second intrathoracic pheochromocytoma that clinically masqueraded as a tumor of the left apical sulcus at the level of the first intercostal space with Horner's syndrome. The patient died of cardiac decompensation and a stroke. Autopsy showed normal adrenal glands, advanced renal arteriosclerosis and a pheochromocytoma in the region of the apex of the left hemithorax.

Thus, the clinical aspects of this disease are variable and may suggest such unrelated pathologic processes as tumor of the superior sulcus, Raynaud's disease, essential hypertension and psychoneurosis.

#### PATHOLOGY

Pathologically, the tumor arises from the pheochromoblast cell. This is to be distinguished from the sympathoblast cell, which represents the anlage of the sympathicoblastomas, or neuroblastomas, a tumor unrelated to the syndrome under discussion. Goldzieher<sup>13</sup> has outlined the genetic development of tumors of the adrenal medulla. These are derived from the parent cell, or sympathogonia, which in the course of embryologic development, differentiates into the sympathoblast and the pheochromoblast. The sympathoblast gives rise to the ganglion cell whereas the pheochromoblast gives rise to the pheochromocyte, from which cell type are derived the cells of the chromaffin system, first described by Kohn,<sup>14</sup> in 1903, as consisting of chromaffin or chromophilic cells found along the entire length of the autonomic nervous system occurring in the autonomic ganglions as nests known as chromaffin bodies or paragangliomas. In addition, the chromaffin system includes the adrenal medulla, carotid body and Zuckerkandl's organ, which comprises two small chromaffin bodies lying anterior to the aorta near the inferior mesenteric artery.

It should be pointed out that although any chromaffin body may at least theoretically develop a tumor called a chromaffinoma or pheochromocytoma, such a tumor need not produce the hypertensive syndrome. Cragg<sup>15</sup> has shown that there is no necessary correlation between chromaffinity and

the presence of epinephrine. Thus, by 1943, 275 cases of carotid-body tumors had been reported, and in none of these was hypertension present. It appears that chromaffinomas of the carotid body do not produce hyperadrenalinemia. Tumors of Zuckerkandl's organ, on the other hand, may or may not produce adrenalin.

The tumors that produce hypertension are usually found to contain increased amounts of adrenalin when analyzed. Normally, the adrenal glands contain 0.4 mg per gram of tissue, but some tumors have been found to contain as much as 20 mg per gram.

The chromaffinoma stains yellow with Zenker's chromate solution, and this chromate fixation is characteristic of the tumor. Cytologically, these tumors consist of polyhedral cells arranged in nests or masses, containing abundant cytoplasm, but varying considerably in size and shape. They often show hemorrhagic cysts.

The tumors may be unilateral or bilateral, benign or malignant. MacKeith<sup>1</sup> showed that 97 per cent were bilateral and 9 per cent were malignant. Thus, in most cases of this syndrome, one may reasonably expect to find a single benign tumor as responsible pathologically for the symptom complex.

There has been an interesting association of cutaneous neurofibromatosis with pheochromocytoma in 9 of the 165 cases of adrenal tumors reported by MacKeith.<sup>1</sup> Most of these have been in bilateral adrenal tumors.

Autopsy studies reported by Howard and Barker<sup>2</sup> revealed that nephrosclerosis was an uncommon finding and that when it was present, it was of mild degree.

#### 1164F (DIMETHYL PIPERIDINOAMINOMETHYL BENZODIOXANE)

Pharmacologic interest in dioxane drugs dates back to 1933, when Fournneau<sup>16</sup> reported synthesis of some of these derivatives. One of these, 933F (piperidino-methyl-benzodioxane), has been studied extensively. In 1934 deVleeschhouwer<sup>17</sup> showed that 933F reverses the hypertension produced by adrenalin in the chloralosanized dog and reduces or abolishes the smooth-muscle response to adrenalin, leaving unimpeded the nerve stimuli.

Katz and Friedberg,<sup>18</sup> in 1939, produced in trained, unanesthetized dogs, a reversal or inhibition of the adrenalin pressor action with 933F in doses of 1 to 5 mg per kilogram of body weight.

Monson and Lissak<sup>19</sup> showed that 933F accelerates the inactivation of adrenalin in vitro.

The theory of Rosenblueth and Cannon<sup>20</sup> regarding the mechanism of this antiadrenalin action of 933F suggests that this dioxane derivative increases the polarization and decreases the permeability of smooth muscle, blocking the passage of adrenalin to its site of action inside the smooth-muscle cell—that is, 933F polarizes the effector cells and thus limits the penetration of circulating chemicals (such

as adrenalin) without affecting the activity of mediators liberated intracellularly by the nerves.

The possible use of benzodioxane derivatives as indicators of hyperadrenalinemia in clinical diagnosis was first suggested by Biskind, Meyer and Beadner<sup>21</sup> in 1941. Previously, the demonstration of hyperadrenalinemia depended upon the modified Pissemaki method of perfusion of a rabbit's ear with blood drawn from a patient having an hyperadrenalinemic crisis—as done by Beer, King and Prinzmetal<sup>22</sup> (1937), who demonstrated a reversal effect with ergotamine. This is a cumbersome test requiring special technical facilities that are not easily available in many laboratories.

The effect of these drugs on experimentally produced hypertension in animals has been studied by Bing and Thomas<sup>23</sup> and by Goldblatt,<sup>24</sup> and it has been shown that renal hypertension is not significantly influenced by the intravenous administration of one of these derivatives, 883F (di-ethyl amino methyl benzodioxane).

Sapirstein and Reed,<sup>25</sup> using 933F intraperitoneally, produced no change in the blood pressure of normal rats and in the blood pressure of rats made hypertensive by the partial ligation of one renal artery.

Recent studies by a group at the Columbia-Presbyterian Medical Center—comprising Dr Henry Aranow, Jr, and Dr Marcel Goldenberg, of the Medical Service, and Dr C. Harrison Snyder, Jr, of the Babies Hospital—suggest that the blood-pressure level in patients with essential hypertension is not significantly influenced by the intravenous injection of 1164F (dimethyl piperidinoaminomethyl benzodioxane), another representative dioxane derivative. These workers thought it reasonable to expect that the blood pressure in patients with hyperadrenalinemia would show a demonstrable fall if one of these drugs were injected intravenously.

When, after the removal of the intra-adrenal tumor, a solution of 1164F was injected intravenously in the case presented above, a significant drop in blood pressure from 160 systolic, 144 diastolic, to a normal level (100 systolic, 60 diastolic) ensued. Upon cessation of the injection, the blood pressure rose to its preinjection level, only to fall to normal again upon repeated intravenous injection of 1164F. The dose of each injection was 15 mg of the dry powder dissolved in 1.5 cc of sterile distilled water given intravenously in a two-minute period during a continuous intravenous drip of physiologic saline solution.

The results of this test suggested the possibility of residual hyperadrenalinemia and therefore the likelihood that residual pathologic adrenalin-producing tissue was still present. Surgical exploration proved this to be so, and the second pheochromocytoma was found and removed.

After both pheochromocytomas had been surgically removed and the blood pressure had fallen to normal levels, the intravenous injection of 1164F was repeated, and no change in the blood-pressure level could be induced, suggesting that hyperadrenalinemia was no longer present and that all the pheochromocytoma tissue had been successfully removed.

Goldenberg, Snyder and Aranow<sup>26</sup> have devised a new test for hypertension due to circulating epinephrine. This is based on the adrenolytic effect of benzodioxane derivatives.

### TREATMENT

The treatment is surgical extirpation of the tumor or tumors, if more than one can be shown to exist. Many reports of dramatic cures have been recorded, and these have recently appeared with increasing frequency. There has been a demonstrable reduction in the operative mortality, and among the last 18 cases reviewed by MacKeith,<sup>1</sup> only 3 deaths occurred—an operative mortality of 16.6 per cent for solitary pheochromocytoma.

Ideal care before and after operation demands the assistance of an internist who, in close co-operation with the anesthetist, will carefully observe the changes in the pulse and blood pressure and regulate the dose of intravenous and intramuscular adrenalin and determine the indications for the administration of adrenal cortical extracts, both natural and synthetic. The importance of atraumatic manipulation of the tumor during operation cannot be overemphasized. The value of adequate surgical exposure is obvious, and if possible the blood supply to the tumor should be occluded before manipulation. During the operative procedure, one may be vividly impressed with the immediate dramatic fluctuations in the patient's blood pressure, because these tumors, although usually histopathologically benign, may be physiopathologically malignant. This fact is illustrated by the case report of Brunschwig and Humphreys,<sup>27</sup> whose patient had a nearly fatal attack of syncope, but finally recovered, and by the case report of Palmer and Castleman,<sup>2</sup> whose patient died before surgical treatment could be instituted.

Tumors have been successfully removed by both the extraperitoneal lumbar approach, with or without rib resection, and the abdominal transperitoneal approach. The latter probably affords a better opportunity for abdominal exploration for the presence of multiple tumors.

In the case reported above the intra-adrenal tumor was removed by a flank extraperitoneal incision, and the extra-adrenal tumor by an oblique subcostal transperitoneal approach.

### DISCUSSION

Pheochromocytoma must be ruled out as a possible etiologic agent in any patient with hyperten-

sion, whether paroxysmal or continuous and unremitting.

Perirenal insufflation of air or some other gas is at times the only nonoperative technic that will help to localize an adrenal enlargement too small to cause demonstrable displacement of the homolateral kidney.

The possibility of multiple pheochromocytomas must be considered in the management of any patient who fails to show a complete and permanent return of the blood pressure to normal after the removal of one pheochromocytoma. Multiple tumors may be present in the same patient, and more than one operation may be necessary to remove, completely, all the pathologic adrenalin-producing tissue present before one may reasonably expect the blood pressure to return to normal levels.

One of the benzodioxane derivatives, 1164F (dimethyl piperidinoaminomethyl benzodioxane), appeared to have given some diagnostic aid in suggesting the presence of hyperadrenalinemia in the case reported.

### SUMMARY

A case of coexisting intra-adrenal and extra-adrenal pheochromocytomas is reported, with a brief discussion of the surgical management that resulted in cure of the patient. This appears to be the first recorded case of surgical cure of multiple pheochromocytomas.

The clinical manifestations of pheochromocytoma are briefly reviewed, and emphasis is placed upon the variability of the symptoms and signs.

The difficulties that are at times encountered in differentiating this disease from essential hypertension, hyperthyroidism, angiospastic states, such as Raynaud's disease, psychoneurosis and diabetes mellitus are emphasized.

Importance is placed on perirenal insufflation of air as an aid in the localization of early enlargements of the adrenal gland that can be identified by no other nonoperative means.

The value of atraumatic surgical technic and of careful administration of adrenalin and adrenal cortical extracts, both natural and synthetic, when indicated, during the operation and postoperatively is stressed.

A report of the depressor effect of 1164F, a benzodioxane derivative (dimethyl piperidinoaminomethyl benzodioxane), injected intravenously, on the elevated blood pressure of a patient suffering from a pheochromocytoma is given, and the possibility that this substance will prove of help in the clinical diagnosis of hyperadrenalinemia is mentioned.

## MEDICAL PROGRESS

### ORTHOPEDIC SURGERY

#### I Conditions of the Shoulder

CARROLL B. LARSON, M.D.\*

BOSTON

IT is the purpose of this report to present as clear-cut a clinical picture as possible of the common conditions affecting the shoulder. More than sixty articles from the literature of the past four years have been reviewed to form the basis of this survey.

Codman<sup>1</sup> so well described all known conditions that his book still represents a standard by which all that is new must be judged. Every writer on a subject pertaining to the shoulder is aware of this, and it therefore follows that anyone concerned with the diagnosis and treatment of conditions about the shoulder should be conversant with Codman's book.

Inman, Saunders and Abbott<sup>2</sup> have studied the function of the shoulder girdle by methods that are new and very promising for the future. Already their analysis of motion in the shoulder has a practical bearing. When the arm is abducted, the muscular apparatus enters into a total, combined effort—that is, the action of the deltoid and supraspinatus working together depend on a simultaneous depressor group striving to hold the head of the humerus "fulcrumed" in the glenoid, namely, the

subscapularis, infraspinatus and teres minor. This tends to disagree with the old concept that the supraspinatus initiates abduction, which the deltoid carries on. Furthermore, muscle transplants, to replace the deltoid, will not be effective, in the opinion of the authors, if there is a loss also in the power of the depressors.

During abduction of the arm, motion takes place in four joints simultaneously: the sternoclavicular, acromioclavicular, scapulothoracic and scapulohumeral joints. For the first 30° of abduction, or what is called the "setting phase," the simultaneous jockeying of these joints for position varies depending upon individual characteristics. Beyond 30° there is a rather fixed pattern in which the ratio of humeral to scapular motion is 2:1. For free and full elevation of the arm, two other conditions are necessary: lateral rotation of the humerus and rotation of the clavicle. The latter allows opening or elongation of the coracoclavicular ligaments. This has a practical bearing on fusion of the acromioclavicular joint. Since a fusion will destroy rotation of the clavicle, it will thereby limit abduction to 90° if the fusion took place with the arm at the

\*Assistant in orthopedic surgery, Harvard Medical School, assistant orthopedic surgeon, Massachusetts General Hospital.

side, whereas abduction will be elevated to  $135^{\circ}$  if the fusion occurred with the arm abducted

It is possible for anyone who examines the shoulder to make further use of shoulder motions in differential diagnosis if the examiner is first aware of the normal pattern. By detecting a variation from this normal pattern, attention can be focused on the particular joint involved that is disturbing the pattern. This procedure is perhaps another way of referring to what Codman<sup>1</sup> has aptly described as scapulohumeral rhythm although it is actually applicable to more joints than were originally considered. This concerns conditions about the shoulder that require careful differential diagnosis, and as a group, they can be classified as causes for painful shoulder. For the purpose of simplification, these causes are discussed below under the headings of calcifications and ruptures of the musculotendinous cuff.

In 1943, Jones<sup>3</sup> studied 600 cases of painful shoulder, and he was startled by the fact that not a single diagnosis of complete rupture of the supraspinatus tendon had been made. At the same time, he was aware that 2 per cent of all shoulders examined at routine autopsy, in patients beyond the age of thirty, showed some degree of tear of the musculotendinous cuff. Codman<sup>1</sup> observed less than 12 complete ruptures, whereas he listed hundreds of cases of incomplete rupture, and yet his own post-mortem studies revealed an approximately equal frequency of large and small ruptures. This indicates that some degree of rupture is a very common occurrence, perhaps more common than is recognized clinically. McLaughlin<sup>4-7</sup> reviewed 3000 cases of lesions of the shoulder of which 275 came to operation. This allowed him to formulate some definite opinions regarding ruptures of the musculotendinous cuff. With the addition of observations from such authors as Howorth,<sup>8</sup> Jones<sup>3</sup> and Gunning,<sup>9</sup> a clinical entity from the standpoint of the underlying pathologic lesion can now be visualized.

Probably most painful shoulders have their origin from the same anatomic fault, which is peculiar to the joint in question. In human beings the shoulder joint is at the mercy of the continuous effect of gravity. There is a rather continuous resistance to gravity by the ligaments and especially the musculotendinous cuff. In addition, the prominence of the outer periphery of the musculotendinous-cuff insertion allows it to be under continuous pressure from the drag of the deltoid. This situation leads to diminished circulatory exchange and thus to local attrition. Attrition produces a weakness in the musculotendinous cuff with the focal point over the supraspinatus insertion. If, to this picture is added excessive use, such as the maintenance of abduction positions for long periods, or faulty use, such as sudden jerky movements, a degeneration is initiated at some point within the structure of the tendon near its insertion. If faulty movements

are then continued in repeated small exertions or one large exertion, as might occur in injury, it is very simple for the tendon to give way at its degenerated point. The amount of this giving way is dependent entirely upon the location and amount of degeneration and of the force applied to the shoulder. Once the giving way has occurred, two courses seem open to nature in dealing with the lesion in the first, which forms the basis for musculotendinous tears, the attrition and degeneration may be of such extent that very little repair is attempted, the defect may remain static, and with repeated use of the shoulder, the lesion may progress, in the second, if sufficient blood supply is still available, nature may attempt to heal the degenerated area, but with repeated use and abuse, the repair process is constantly thwarted, causing an accumulation of an excessive amount of inflammatory granulation repair into which calcareous material can be deposited. This forms the basis for calcification of the musculotendinous cuff or what is commonly termed bursitis. It is possible that tears and calcification are part of the same original pathologic process based on the anatomic peculiarities of the shoulder.

#### CALCIFICATIONS OF THE MUSCULOTENDINOUS CUFF

It has been aptly stated that bursitis is no more a diagnosis than headache or jaundice, and yet the common usage seems justified because the bursa actually is secondarily involved, to a greater extent, than in cuff tears and this helps to separate the two conditions clinically.

The basic lesion has already been described but needs further elucidation. Why calcification occurs and the actual chemical nature of the calcification is not known. The fact remains that it does occur and that the location corresponds with the degenerated area within the rotator cuff. Operative findings have shown that the degree of inflammation varies in accordance with the amount of irritant material in contact with the bursal floor. This irritant material may be composed of degenerated tendon debris with or without calcification. If the same material lies deeper in the tendon, less inflammation is produced in the bursal floor, and the pain is apt to be less. However, another source of pain seems to be from tension built up within the calcareous deposit. This is borne out clinically by releasing the calcareous deposit with relief of pain. Since calcification is not always present when there is pain, the pain must be produced by inflammation of the bursal floor secondary to degenerated tendon debris. In this type of case needling is apt to be less efficacious. The pain that is present depends upon the amount of inflammation and the tension within the calcareous deposit. There is little correlation between the clinical and roentgenographic features of the disease.

It has been shown that degeneration can occur with diffuse deposition of calcium without evidence of a tear. On the other hand, it is common to find degeneration, inflammation and calcification in the presence of tears. This indicates that bursitis and tears commonly coexist and that the clinical differentiation must be on the preponderance of tendon disruption (internal derangement), which persists, versus inflammation and calcium deposition, which may or may not persist. Histories of repeated attacks of painful shoulder for periods as long as ten to fifteen years are often obtained, but autopsy findings have shown that calcification is rare after sixty-six years of age, whereas cuff tears, without surrounding inflammation, are not uncommon. The basic reason for the reversibility of bursitis as compared with cuff tears is unknown.

It is well known that the relief of pain from an acute attack may spontaneously occur, and although repeated attacks may supervene, the disease is eventually self-limited unless associated with tears that persist. Because of the frequency of spontaneous relief (the actual percentage is unknown) it becomes difficult to evaluate benefits of treatment. The only difference between acute and chronic lesions is the degree and extent of inflammation and the consistency and tension of the material in the deposit.

Treatment can be considered either curative or palliative. In any case one must first determine whether symptoms, by reason of their severity, duration and cause for disability, warrant curative or palliative procedures. The only curative procedure is generally agreed to be operative, and the operation is usually accomplished with a small muscle-splitting incision through the anterior deltoid muscle and evacuation of the calcareous deposits with excision of the degenerated portion of the tendon. A simple sling, mild heat and exercises will then tend to restore the arm to normal, usually within a period of two or three weeks, the pain will have subsided, and within six weeks the motions will be restored.

Palliative procedures are variable and somewhat more difficult to evaluate. The more frequent of these is needling of the lesion under local anesthesia. In needling, an attempt is made to reach the calcareous deposits and remove as much as possible through the needle. This is sometimes facilitated by the use of saline solution to dilute the deposit. X-ray examination, at times, is a helpful guide to be sure that the needle is within the confines of the deposit. Some authors believe that by perforating the tendon overlying the deposit, sufficient material will escape through the puncture wound to effect relief of pain. It seems reasonable that the needling method can in no way rid the tendon of its degenerated area.

Many authors have advised x-ray therapy, the usual dose being approximately 150 r at 8 ma

200 KV through 1.5 mm of copper, in addition to 1 mm of aluminum filter with a 50-cm target-skin distance. One to three such doses over a period of one week are necessary. All advocates of this method indicate good results in acute bursitis, but the follow-up studies are not of long enough duration and sufficiently detailed to include the time for recovery, the amount of motion gained or the number of calcific deposits eradicated. It therefore remains unsettled whether x-ray therapy actually relieves a greater percentage than if the disease is left to spontaneous recovery. Perner<sup>3</sup> advises the use of intravenous iron cacodylate as a curative agent.

#### RUPTURES OF THE MUSCULOTENDINOUS CUFF

Because of the similarity of underlying lesions of the musculotendinous cuff, it is difficult to differentiate tears from bursitis, but certain points should be kept in mind as being helpful. If cases are analyzed for type of pain, residual-motion defects and the course of the complaints, it should be possible to tell one from the other in most cases. It seems reasonable from the foregoing that in the acute stages, diagnosis may be quite impossible. Furthermore, it is quite unnecessary to make an accurate diagnosis in the early phase of rupture because the lesion is an old one to start with, and the treatment will be no more effective if done early than late. This disagrees somewhat with Codman,<sup>4</sup> who insisted that tears should be operated upon from the moment of their diagnosis, preferably in the acute phase. Once the acute phase has passed, the signs in the shoulder will become somewhat clearer. As a rule, there will be no continuous pain, but rather the complaint will be that of discomfort on a certain motion, particularly at a definite point in the arc of that motion.

Upon examination there will be much less limitation of passive motion than would be expected. Scapulohumeral rhythm will be disturbed. Inability to initiate abduction is not a good diagnostic sign because the remaining musculotendinous cuff may exert sufficient depressor effect to enable the deltoid to carry out abduction. Perhaps a better test would be to determine the inability to maintain abduction against resistance, with the arm first in external and then in internal rotation. In this way, the lesion may be more accurately placed in the anterior or posterior quadrant of the musculotendinous cuff. At times, local palpation may reveal a sulcus if the tear is sufficiently large, or there may be a comparatively painless click when the torn portion slides under the acromion. These signs, when present, are helpful but in no way completely diagnostic. At times the diagnosis can be made only by surgical exploration. The only indication for surgery, however, is for pain or disability sufficient to make such a procedure worth while from the patient's point of view.

It is quite generally agreed that the majority of minor tears heal spontaneously under conservative treatment. It is more likely that the minor lesions heal in spite of treatment, and because many do heal, it is wise in any given case to use a therapeutic trial of conservatism. Should the symptoms continue to the point where the patient seeks further treatment, it is generally agreed that the only effective treatment is surgical. The actual surgical attack is about as varied as the number of surgeons describing it.

McLaughlin<sup>6, 7</sup> has described an exposure with the skin incision paralleling the suspender line just lateral to the acromioclavicular joint. The acromion is then osteotomized to give adequate exposure of the shoulder cuff. This has the virtue of avoiding the nerve supply to the deltoid. It has the added advantage of removing the acromion if this is deemed necessary to give the repair more room.

A second approach is the anterior deltoid splitting, which can be enlarged by releasing the upper attachment of the deltoid from the acromion if it becomes necessary. Care must be exerted in the use of this incision to avoid injury to the axillary structures during medial retraction, and occasionally, some of the nerve supply may be lost to the anterior fibers of the deltoid.

In either approach, once exposure has been accomplished, the attention is directed to locating the tear. Most of the time, this will not be difficult if the operator is aware that incomplete tears may not be visible from the surface. In such cases, by creating an opening at the periphery of the cuff in the area under suspicion, the tear can be located. Tears of the rotator cuff are so varied that no two are alike, but in general, they are either transverse near the insertion of the cuff or longitudinal, usually between the tendon of the subscapularis and supraspinatus. It is sometimes difficult to visualize in which direction the initial tear might have started because there is a tendency, with continued use of the shoulder, for the tear to progress and the edges to retract. What appears to be a longitudinal tear may have started as a transverse one.

Once the tear has been visualized, it becomes an individual problem to determine the type of repair. In general, the small tears can be resutured to their original point, especially the transverse variety, by mattress sutures through the bone. The longer retracted tears may require side-to-side repair to avoid tension. Capsular flaps, such as that described by Jones,<sup>8</sup> may be helpful in repairing this type of defect. At times the retraction may be such that end-to-end apposition cannot be obtained, and the torn edge may need transplantation to the head of the humerus at a point more medial than the original insertion. In any event, the postoperative care will be quite similar in all cases, taking into account the amount of repair necessary. Three to six weeks are allowed for tissue healing, and the

affected arm is immobilized in a sling. Active exercises are then started, and usually within a period of three months, shoulder motions will be restored. In severe tears such as complete avulsions of the entire cuff, motions will be restored to 50 per cent of normalcy. In some cases, certain authors have advised shoulder fusions for these severe injuries. On this point there is no unanimity, and the solution should remain an individual one in each case.

#### PERIARTHRITIS

Quite apart from bursitis or rotator-cuff tears, a clinical entity that occurs in the shoulder has been discussed by authors such as Tarsy,<sup>10</sup> Wilson,<sup>11</sup> Neviaser<sup>12</sup> and others<sup>13, 14</sup>. Codman<sup>1</sup> referred to this group as tendinitis of the rotators. Wilson described it as periarticular adhesions, and it has been referred to as adhesive capsulitis. The actual cause of this condition is unknown, but because it occurs with such uniformity between the ages of fifty and fifty-five, particularly in women, it is suggestive evidence that there is an underlying endocrine imbalance. Against this hypothesis is the fact that it usually remains localized to one shoulder.

Several points set this lesion apart from other shoulder conditions. Upon exploration the subacromial bursa has usually been found uninvolved, tears and calcifications are very infrequent, there has been general fibrosis, which fixed the periarticular structures at their insertions, limiting not only direct shoulder motion but also scapulothoracic motion, there are seldom localized areas of discomfort, but instead, the entire shoulder seems tender and painful, x-ray films, as a rule, show nothing other than decalcification, and there is an absence of traumatic history. In follow-up studies practically all these shoulders become normal within an average period of two years, and certain experiences have led away from surgical treatment. In a follow-up study reported, the rehabilitation period in 34 patients averaged five months. This was accomplished by repeated novocain injections either locally or as block anesthesia combined with repeated careful mild manipulations, as well as daily exercises on the part of patients. In addition to local treatment, particular attention is paid to general therapeutics, correction of endocrine disorders and so forth.

#### FROZEN SHOULDER

Throughout the literature, the use of the term "frozen shoulder" carries only the connotation of a shoulder that has lost entirely its active and passive motion. Many conditions have been described as a cause, such as bicipital tenosynovitis, subacromial bursitis, partial and complete ruptures of the rotator cuff and dislocations and elongations of the biceps tendon. Lippmann<sup>15</sup> pointed out that bicipital tenosynovitis is a common cause, and he explored 32 cases of frozen shoulder. All showed inflammatory changes of varying degree in the

biceps tendon and sheath, and only a few showed bursal lesions. Tarsy,<sup>16</sup> on the other hand, tried to separate each of the above conditions as clinical entities, but the symptoms and signs are not clear-cut so that in the present state of knowledge, these diagnoses may apply when the condition does not fit the well known entities. It is also possible that they represent complications or extensions of the inflammatory process accompanying bursitis and cuff tears.

#### RECURRENT DISLOCATION OF THE SHOULDER

The writings of several authors, including Henderson,<sup>17</sup> Gray,<sup>18</sup> Bost,<sup>19</sup> Wellington,<sup>20</sup> Magnuson,<sup>21</sup> Crosby<sup>22</sup> and others, have been reviewed in an effort to find out if there has been any clarification regarding the causative factor in recurring dislocations of the shoulder. Practically all reiterate Bankart's conception that an injury to the glenoid ligament is an essential factor in allowing dislocations to occur. Magnuson<sup>21</sup> has added the concept that there is a lack of muscle balance, which fails to resist the downward and forward displacement of the head, and hence he has outlined the restoration of this balance by shifting the subscapularis muscle.

The surgical procedures advised for the correction of recurrent dislocations are varied, but in general, the once popular Nicola procedure has lost some favor because the tendon frays off when put to hard usage. There still seems to be a place for the Nicola<sup>23</sup> procedure except in patients who are expected to make vigorous use of their arms. Bankart's operative repair is quite generally accepted. However, it is subject to modifications such as the addition of reinforcing fascia or osteotomy of the glenoid. In general, it seems that there is no selection of choice and that the operator, in each case, must repair what seems necessary after noting the defects present at the time of operation. There are very few adequate follow-up series to help in the selection of operative procedures. In cases followed for more than one year, Henderson<sup>17</sup> reported a 91 per cent cure using his own tenosuspension operation. Shepherd<sup>24</sup> strongly urges the search for loose bodies in each case of repair for recurring dislocations. In old dislocations that are irreducible, Steindler<sup>25</sup> has advised arthrotomy, with replacement of the head and reconstruction of the capsule.

#### ACROMIOCLAVICULAR DISLOCATIONS

There is no unanimity of opinion regarding the diagnosis or treatment of dislocations of the acromioclavicular joint. Most authors, however, agree that dislocations of this joint can be partial, when the acromioclavicular ligaments are torn, or complete, when the coracoclavicular ligaments are torn. In partial dislocation many types of conservative fixation are advocated, such as a modified Lever-type sling by Goldberg,<sup>26</sup> a strap brace advocated by

Giannestras<sup>27</sup> and a webbing strap shoulder spica as described by Wolin.<sup>28</sup> No one has presented a good picture of end-results comparing the treated with the untreated partial dislocations. This perhaps accounts for the fact that these many methods of treatment are about equally successful. Only an occasional case of partial dislocation is disabling. Bloom<sup>29</sup> advocates early reduction in all cases and maintenance of reduction by wires to give fixation while the ligaments are going through their primary repair. These wires are removed two months later. Bloom, following this form of treatment, returned 12 men to full military duty, but in his opinion it would take a considerable series of treated versus untreated dislocations to prove that the primary treatment in all cases should be routine wiring. Urist<sup>30</sup> found that conservative treatment led to a stable painless joint in 80 per cent of partial dislocations.

Soule<sup>31</sup> has pointed out how x-ray films may be taken to demonstrate mild or severe acromioclavicular separations. With an anteroposterior roentgenogram of both shoulders taken in the upright position with a 20-pound weight in each hand, widening of the involved joint and elevation of the acromial end of the clavicle will be demonstrated. The mere presence of a demonstrated separation does not preclude surgical treatment unless it in some way interferes with the efficiency of the patient, and there are many reported methods of surgical attack to restore the patient's efficiency. Mumford<sup>32</sup> believes that the clavicle, either as a whole or in part, may be excised without impairment to the shoulder girdle. He recommends excision of the distal 2.5 cm of the clavicle for painful recurrent separations or for chronic arthritis of the acromioclavicular joint. In his hands, 9 cases resulted in satisfactory function with freedom from pain. Urist<sup>30</sup> agrees that this treatment will give a painless shoulder, but strength will not quite equal that of the normal shoulder.

Other forms of treatment have been discussed toward stabilizing the joint. Birkett<sup>33</sup> reported a repair with fascial strips, and follow-up x-ray studies revealed considerable ossification of the new fascial ligaments, the patient had stability and strength of the shoulder with some limitation of scapular and arm movements. Soule<sup>31</sup> has reported similar ossification as early as twenty-two days after injury. He further states that if ossification has not appeared within six weeks after injury, it was not noted in subsequent examinations. Furthermore, the ossification did not seem to bear any relation to type of treatment or to contribute to any disability but actually might aid in restoring continuity of the damaged ligament.

#### MISCELLANEOUS CONDITIONS

Much has been written regarding the treatment of injuries about the shoulder joint, especially as an outcome of the experience in World War II. There

is nothing particularly new that does not relate to similar injuries elsewhere. Parnall<sup>34</sup> has reported a reconstruction in 2 cases in which there was gross shell destruction of the shoulder joint. The lack of adequate follow-up study has kept such reports from being instructive, although they are very interesting. Pendergrass<sup>35</sup> has given a discussion of neuroarthropathies as they pertain to the shoulder that well sums up what is presently known regarding such conditions. Camiel<sup>36</sup> has presented an excellent description of the progressive x-ray findings in tuberculosis of the shoulder and has attempted to correlate the x-ray with the clinical findings. He believes that no individual x-ray sign is pathognomonic but that, when the films are taken in progressive sequence, the diagnosis will be apparent. Hendricks<sup>37</sup> has reviewed the scalenus anticus syndrome and reported 4 cases. The point of most importance and interest regarding the shoulder joint is the exclusion of the shoulder in the differential diagnosis by the finding of no tender points and a normal range of motion.

Regarding diseases about the shoulder joint, such as arthritis, sepsis and tumors, there is very little new that is of interest. Smith-Petersen<sup>38</sup> has advised acromioplasty as a surgical procedure in rheumatoid arthritis. This is particularly indicated for removing a source of pain and thereby for allowing freer use of not only scapulohumeral but also scapulothoracic motion.

Rowe and Yee<sup>39</sup> have described a posterior approach to the shoulder joint, and McKeever<sup>40</sup> has covered in detail the problem of amputations and prostheses for the upper extremity.

\* \* \*

In conclusion it should be apparent to all that in the differential diagnosis of painful conditions about the shoulder joint, the examiner must be constantly aware of distant lesions which produce radiation pain to the shoulder. Anyone interested is referred to a discussion of this problem by Bosworth.<sup>41</sup>

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

### Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

### CASE 34201

#### PRESENTATION OF CASE

A thirty-two-year-old woman entered the hospital complaining of occipital headache and increasing drowsiness.

Eight years prior to admission a diagnosis of pulmonary tuberculosis was made by x-ray and sputum examination. The patient was treated by artificial pneumothorax for five years, after which the sputum was negative and the disease was thought to be arrested. Sixteen months before entry she began to have steady pain in the left lower quadrant. Two months later an abdominal operation was performed at another hospital, and a "mass of adhesions" was found. No organs were removed. The patient seemed to improve, but six months before admission a mass appeared in the left lower quadrant. This was diagnosed as a pelvic abscess, and was incised and drained at still another hospital. Cultures of the pus were negative. Guinea-pig inoculation was not done. A fecal fistula developed and drained intermittently up to the time of admission. Eight days before admission the patient complained of a heavy feeling in the head, and had a temperature of 102°F. Two days later she developed occipital headache, followed by nausea, increasing drowsiness and diplopia. Her physician found that the temperature was normal, and no neck rigidity was present.

On physical examination the patient was very drowsy, apathetic and slow to answer, but oriented and coherent. The heart and lungs were normal. There was a midline suprapubic scar with a 3 mm opening discharging small amounts of greenish-brown liquid and soft, solid material, which resembled feces but was odorless. Pelvic examination revealed a moderately tender mass about 12 cm in diameter, apparently consisting of uterus and adnexa matted together. The neck was not stiff, and there was no Kernig sign. The vision, fundi and visual fields were normal. The pupils were 1.5 mm in diameter and equal, and reacted to light and accommodation. There were no gross ocular palsies, but upward gaze seemed somewhat limited. Convergence was good. There was diplopia on looking in any direction except upward.

One examiner noted slight weakness of the right external rectus muscle. The facial muscles were thought to be slightly less active on the right. Hearing was reported by several different examiners to be diminished on the right, but quantitative tests were not done and Rinne and Weber tests were negative. Other cranial nerves were normal. Motor findings were normal. The tendon and abdominal reflexes were normally active and equal, and plantar reflexes were normal. Sensation was normal.

The temperature was 98.6°F, the pulse 80, and the respirations 20.

Examination of the blood disclosed a hemoglobin of 15 gm and a white-cell count of 25,000, with 85 per cent neutrophils. The blood non-protein nitrogen was 23 mg., the total protein 8.12 gm and the fasting blood sugar 112 mg per 100 cc. The blood Hinton test was negative. Repeated urine examination and urine cultures were negative. The spinal-fluid pressure was equivalent to 260 mm of water, with normal dynamics. The fluid contained 64 white cells per cubic millimeter, with 72 per cent lymphocytes, 15 per cent polymorphonuclear leukocytes and 12 per cent monocytes, the total protein was 116 mg and the sugar 120 mg per 100 cc., and the chloride 124 milliequivalents per liter. The colloidal-gold wave was 2223333111,

and the Wassermann test was negative. A guinea-pig inoculation was negative.

X-ray study of the chest showed numerous linear areas of increased density in the right upper lobe and, to a slight degree, in the left midlung field. There was no evidence of cavitation. Skull films were normal. An electroencephalogram showed high voltage and slow waves bilaterally, most prominent in the frontotemporal and parietal regions and probably somewhat more marked on the left. Streptomycin was given intrathecally (50,000 units twice a day) and intramuscularly (0.4 gm every six hours). Penicillin was given intramuscularly (50,000 units every three hours).

During the first week the patient did not improve. The temperature remained normal. Drowsiness and headache became more pronounced. Moderate rigidity of the neck and a positive Kernig sign were present. The margins of the optic disks were slightly blurred. On the sixth and seventh days weakness of the left arm and leg developed. The tendon reflexes were active and equal, and the plantar reflexes were normal. Bilateral occipital burr-hole exploration on the seventh hospital day was negative, and a ventriculogram was normal. The cerebrospinal-fluid pressure remained above 300 mm, and two days later a right subtemporal decompression was performed in an attempt to relieve the increased intracranial pressure. On the next day the left hemiparesis improved, and the right became less drowsy. On the fifteenth hospital day coarse nystagmus on right lateral gaze was observed. This cleared up during the next week. During the next six weeks there was slow improvement, the mental status became normal, and the patient was able to sit in a chair. She complained of slight dizziness, but there was no vertigo. The temperature remained normal. Approximately two months after admission, the patient was able to stand and walk without difficulty. She continued to have mild headaches. The tendon reflexes were very brisk, and there was bilateral ankle clonus, but neurologic examination was otherwise negative. Streptomycin, intrathecally and intramuscularly, and penicillin were given without interruption. During the next few days the area over the subtemporal decompression became tense and bulging. The spinal-fluid pressure rose to over 300 mm, and headache, accompanied by vomiting, increased steadily in severity. Seventy-one days after entry the patient was found dead.

#### DIFFERENTIAL DIAGNOSIS

DR RAYMOND D ADAMS\* May we see the x-ray films?

DR STANLEY M WYMAN Films of the chest show a rather extensive process involving the right upper lobe, with considerable retraction and collapse of the right upper lobe, the hilus being dis-

placed inward. There is also a linear area of fibrotic density in the left midlung field and the left first interspace. The heart shadow is not remarkable. The diaphragm is symmetrical. The spleen is rather large, within the upper limits of normal in size. One cannot exclude activity in the pulmonary process. Films of the skull, I believe, show the posterior clinoids to be a little sharper than usual, and there is a suggestion that the right posterior clinoid is eroded on two films. Air studies are incomplete and not ideal. They show no gross dilatation or displacement of the ventricular system.

DR ADAMS There is no evidence of a destructive process in the mastoid region? There is nothing to suggest a tuberculous infection of the medulla or mastoid cells?

DR WYMAN No, I think that the mastoid cells are well aerated from the available films. There is no evidence of acute bone destruction or erosion.

DR ADAMS It seems from the data submitted that we must assume the patient had tuberculosis. This was established by x-ray films of the chest, sputum examination and the later development of a sterile abscess in the pelvis and of a fecal fistula. The pain in the left lower quadrant, which appeared sixteen months before entry, was probably the first manifestation of tuberculous salpingitis. There is no mention of either gastrointestinal or genitourinary symptoms, but since the pain was in the left quadrant, salpingitis is more likely than tuberculous infection of the descending colon. Tuberculosis more often involves the ileum or cecum, and if this had happened, the pain would have been periumbilical or in the right lower quadrant. Moreover, if a tuberculous ulcer had eroded through the bowel wall to give the pelvic abscess that was found later, it should not have been sterile, colon bacilli should certainly have been cultured. I am unable to settle the point whether the pelvic abscess came from the fallopian tube or the bowel.

The symptoms that appeared during the last phases of the illness were clearly neurologic. The occipital headache, drowsiness and nausea are the first indications of this central-nervous-system extension and could be explained by meningeal irritation as in a leptomeningitis or by a space-consuming lesion in the posterior fossa. The cerebrospinal fluid does not entirely decide which of these two mechanisms was operative. There were pleocytosis and elevation of protein, meaning in all probability that there was some localized or diffuse meningeal inflammation, but the elevated blood sugar is against a bacterial infection in the subarachnoid space. With such an infection, the cerebrospinal-fluid sugar would have been low—below 40 mg per 100 cc. Elevated cerebrospinal-fluid sugar is always related to a high blood sugar, either from diabetes mellitus or, as in this case, with no glycosuria, from injection of glucose intravenously. The cerebrospinal-fluid pressure was

\*Assistant professor of neurology, Harvard Medical School.

elevated, and I am therefore inclined to explain at least part of the patient's drowsiness, slowness in response and apathy, as well as the slow waves bilaterally in the electroencephalogram, on the basis of elevated intracranial pressure. In view of the absence of stiff neck and the findings in the cerebrospinal fluid, I assume that there was a local meningeal infection but not a diffuse tuberculous meningitis.

Are there any neurologic findings that give us a clue to the location of this pathologic process? There are. The right abducens muscle was weak, and the patient had diplopia quite early in the illness — before, I should think, it would have developed as a false localizing sign of increased intracranial pressure. The tests of ocular movement are not well worked out, but I suppose that she had a partial right-sixth-nerve palsy. The right-facial-muscle weakness points to involvement of the seventh cranial nerve, and the partial deafness, about which there was some doubt, to the right auditory nerve. Later there were a left hemiparesis, which cleared up after a few days, and nystagmus on looking to the right. All these symptoms indicate a lesion in the lower pons on the right side, probably in the middle cerebellar peduncle, which disturbed the function of but did not directly invade and destroy the right sixth, seventh and eighth cranial nerves in their intrapontine course, the vestibular nuclei and the right corticospinal tract. A slight inco-ordination of the right arm and leg is all that I need to complete the picture for a cerebellopontine lesion. The absence of ataxia, I suppose, means that involvement of the cerebellar peduncles or hemisphere was not extensive. It must be admitted that the left hemiparesis, which disappeared after the right subtemporal craniotomy, could have been due to a lesion in the right internal capsule or posterior part of the frontal lobe. The cranial-nerve palsies would then have been unrelated.

Up to this point I have persuaded myself that the patient had generalized tuberculosis, not miliary, and that the recent development consisted of a tuberculoma in the lateral part of the lower pons or possibly here and in the right frontal lobe, which produced some elevation of intracranial pressure and localized inflammation of the adjacent leptomeninges. I assume that the physicians who were responsible for this woman's care were of the same opinion because they took the trouble to inoculate a guinea pig, which remained healthy, and proceeded to administer streptomycin. The ventriculogram was probably done to obtain more information regarding the locality of the disease and the temporal craniotomy.

Are there any other diseases that could produce this same clinical picture? Yes, two other possibilities must be considered. Torula may be combined with tuberculosis. One of our patients had

pulmonary tuberculosis and lymphadenitis, established by biopsy and culture, and then developed a torular infection of the lungs and meninges, which proved fatal. The cerebrospinal-fluid changes are very similar to those in tuberculous leptomeningitis except that the cultures are repeatedly negative for tubercle bacilli and the fungus can be seen or cultured. In the case under discussion the abdominal lesion and the fecal fistula are against torula.

The other possibility is that a mixed bacterial infection developed in a patient who already had tuberculous lesions. Either the lung or the pelvic abscess could have been secondarily infected by other pyogenic bacteria. The brain lesion or lesions would then have been metastatic abscesses. In our pathological material we recently had a case of pulmonary tuberculosis in which there was a subsequent development of hemiplegia and signs of increased intracranial pressure and of meningeal irritation. The neurologic signs were found at autopsy to be caused by a large putrid abscess in the left frontoparietal region. There was a mixed flora of bacteria in the abscess, — fusiform bacilli, spirochetes and an anaerobic streptococcus. I can neither affirm nor deny this possibility in the case under discussion. I suppose that if the cerebrospinal fluid had on repeated examinations contained a normal sugar, one would have had to think seriously of this possibility, but without knowing the subsequent cerebrospinal-fluid findings I would not venture this diagnosis.

Tumor of the lung, with metastases to the brain and other organs, is a remote possibility.

#### CLINICAL DIAGNOSIS

Tuberculous meningitis, probable

#### DR ADAMS'S DIAGNOSES

Pulmonary tuberculosis  
Generalized tuberculosis, with tuberculous salpingitis  
Fecal fistula  
Tuberculoma, right pons and cerebellar peduncle and ? left frontal lobe  
Tuberculous meningitis

#### ANATOMICAL DIAGNOSES

*Pelvic abscess*  
*Brain abscesses, multiple*  
Pulmonary tuberculosis, healed  
Operative wounds — subtemporal decompression, ventriculogram, appendectomy, old

#### PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: The systemic findings at autopsy were comparatively few. There was a good-sized tubo-ovarian abscess, and the small

bowel had become adherent to it. There was a closed fistulous tract between the small bowel and the anterior abdominal wall. I think it possible that that fistula never drained. That is perhaps the reason why there was no culture. We could find no evidence of tuberculosis in the walls of the abscess, and the lung showed minimal evidence of tuberculosis — no cavity and only a fibrous scar at the site where the lesion had been, and a little compensatory emphysema.

Dr. Kubik will tell the rest of the findings.

DR. CHARLES S. KUBIK: At autopsy there were signs of generalized increased intracranial pressure in the form of flattening of the cerebral convolutions, cerebellar pressure cones and enlarged ventricles. There was no visible generalized, subarachnoid exudate over the brain or spinal cord, — not even a definite thickening or cloudiness of the arachnoid membrane, — but there was a prominence of the inferior portion of the right cerebellar hemisphere, which was soft and fluctuant and turned out to be an abscess. Projection of the cerebellum into the foramen magnum — that is, a cerebellar pressure cone — unquestionably caused compression of the medulla and death from respiratory paralysis. There were also small abscesses in the right frontal lobe. All the abscesses had thick capsules, indicating that they had been present for some time, a matter of weeks at least. The cavities were filled with thick, greenish-gray pus. There were no tubercles either in the meninges or in the walls of the abscesses, and tuberculosis can be ruled out by the gross and microscopical findings. Smears were negative, and I was not able to find any organisms in sections of the abscesses or of the meninges.

DR. MALLORY: One anaerobic culture from one of the brain abscesses grew colon bacilli. It is a very unsatisfactory organism to find, since one never knows how to interpret it.

DR. KUBIK: Perhaps more attention should have been paid to the nystagmus, weakness of the sixth and seventh nerves and diminution of hearing, but apparently these signs were not very definite. The only explanation we have for the hemiparesis is the large abscess of the cerebellum pressing against the medulla. I do not believe that the small abscesses in the right frontal lobe could have accounted for the left-sided weakness that was present for a while and later apparently subsided. The ab-

scesses were multiple, unquestionably metastatic, and the only possible source that was found was the infection in the pelvis, though metastatic abscesses of the brain from other regions than the lungs are rare. There were no definite abnormal findings in the spinal meninges, spinal cord or nerves of the cauda equina, resulting from the prolonged use of large quantities of streptomycin.

## CASE 34202

### PRESENTATION OF CASE

A twenty-three-year-old man entered the hospital complaining of severe shortness of breath.

He was discharged from the Army one and a half years before entry, when no abnormalities were noted. He was apparently well until three months prior to admission when he began to notice poorly localized and shifting pain in the right side of the chest, without radiation to the shoulders. Soon he began to have profuse night sweats but had no cough, hemoptysis or dyspnea. About three weeks before entry he developed shortness of breath upon exertion. This symptom rapidly increased in severity so that he slept very poorly at night, and he had to sit up in bed to breathe. A physician found fluid in the right side of the chest, and a subsequent thoracentesis produced about "a quart" of bloody fluid. An x-ray film taken after removal of the fluid showed a questionable tumor of the lung. Although the dyspnea was somewhat relieved by the thoracentesis, other symptoms, such as epigastric fullness, anorexia and brief bouts of diarrhea, began to occur. The patient had lost 15 pounds in the two previous months. He denied any contact with tuberculosis.

Physical examination showed a well developed and well nourished man who was mildly dyspneic while sitting up in bed. No superficial lymph nodes were palpable. There was an acneform rash over the chest and back. There was flatness over the lower two thirds of the right lung field, and breath sounds were absent over this area. Coarse breath sounds were heard at the right apex. The left lung was clear to percussion. The rest of the examination was negative.

The temperature was 98°F, the pulse 90, and the respirations 24.

Examination of the blood revealed a red-cell count of 5,120,000, with a hemoglobin of 13.6 gm., and a white-cell count of 17,800, with 74 per cent neutrophils, 22 per cent lymphocytes and 4 per cent monocytes. The urine was normal.

Review of the x-ray films taken at another hospital and those taken on admission showed a massive, right-sided pleural effusion, with a shift of the mediastinum and heart to the left. Bucky films revealed a complete collapse of the right lung, the lateral border of which appeared lobulated. The right main bronchus was seen to a point about 2.5 cm. below the carina, where it ended abruptly. There were several areas of increased circular density, varying in size from 1 to 1.5 cm. in diameter, overlying the collapsed lung and farther out in the region of the eighth rib posteriorly. The diaphragm was not seen on the right. The left lung was well aerated, and no changes were noted in its parenchyma.

On the day after admission an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR CARROLL C MILLER. One immediately jumps to the query, What was the operation performed? It is extremely unlikely, in this hospital at least, that a thoracotomy would be performed on a patient the day after admission unless for an emergency condition. My assumption is that the operation was a bronchoscopy, which should be included as a part of the investigative program.

The highlights of the data given are quickly summarized. In the past history we have a short period of illness. The patient was apparently well on discharge from the Army one and a half years before admission, and the first sign of illness presumably occurred only three months before he was seen here. As a bit of negative evidence he had no contact with tuberculosis. This, of course, may be of equivocal value. In the present illness the salient facts are pain in the right side, night sweats, dyspnea, disturbance of the gastrointestinal tract, with anorexia, epigastric fullness, diarrhea, weight loss, bloody fluid in the chest and the question of a tumor in the lung. Two interesting and probably important negative data are no history of cough and no hemoptysis. When the patient was admitted examination showed signs of fluid in the right side of the chest. There were signs of con-

solidation or perhaps of transmission of tracheo-bronchial breath sounds at the right apex. On the unaffected side again there were no palpable lymph nodes. The left lung was clear. The abdominal examination was presumably negative. The laboratory data do not indicate much except a mild hypochromic anemia and a definite leukocytosis without significant elevation of neutrophils. The x-ray films show effusion, an apparently lobulated lung, bronchial obstruction and areas of circular density overlying or perhaps in the right lung. The left lung was normal. May we see the x-ray films?

DR STANLEY M. WYMAN. I am sorry I cannot demonstrate all that the record describes because the most valuable films were those taken immediately after the removal of the fluid. The areas of density described in the lung are not visible on these films. All we can see is a massive effusion with a fluid level at this point and the collapsed rim of upper lobe, which appears to be normal in thickness and contour. There is no appreciable thickening of the pleura in this region. The heart and mediastinum are displaced toward the left. There is a poorly seen area of round density lying behind the heart on the left side, to the left of the spine. I do not believe this is accounted for entirely by the aorta. The patient was a young man, and I would not expect the aorta to have this wide sweep. Recalling the film taken at the other hospital, which I happened to see, I was not impressed by the obstruction to the bronchus described in the record, and I am not too sure that it was a valid finding.

DR MILLER. Could this line be the left pleura pushed over by a mass in the mediastinum or arising from the right side of the chest?

DR WYMAN. I think so. The left lung is clear. There is no bony disease on the left. On the right it is impossible to exclude it. The later film shows no defect in the bones. The film taken in the upright position shows air in the pleural cavity, and there is now a suggestion of some thickening of the parietal pleura.

DR MILLER. From the description of these x-ray films, should I minimize to a certain extent the report about bronchial obstruction seen on the films taken elsewhere and also the areas of circular density?

DR WYMAN I would not minimize the latter I think they were present. There were nodular densities that appeared to be over the surface of the lung rather than actually inside it. I cannot demonstrate them on these films.

DR MILLER At any rate, they were clearly seen and may be evidence of extension or metastases from a tumor or some other process outside the primary focus.

Let us analyze the symptoms and signs from a positive standpoint. This patient started out with pain in the right side of the chest. This may have been pleurisy — dry at first. Was this a pleurisy-like pain? The description given in the record does not say. The pain may have been due to invasion of nerve trunks in the mediastinum or chest wall. I cannot explain the shifting nature of the process on the basis of either pleurisy or tumor involvement. It is true that pleurisy very frequently jumps from one place to another but certainly is not likely due to movement of fluid. The patient's dyspnea may have been due to the accumulation of fluid in the right side of the chest or to some degree of bronchial obstruction leading to collapse of the lung on that side. He had a 15-pound weight loss. This may have been caused by infection or a malignant lesion. He had a bloody pleural effusion. Serous effusion due to systemic disease, such as a cardiorenal condition, would not be bloody. If this was an infectious process, the most likely diagnosis is tuberculosis. It is comparatively rare for the ordinary effusion of intrapulmonary tuberculosis to be bloody. The incidence of bloody effusion with tuberculous pleuritis, on the other hand, is notable. Infarction of the lung could have caused a bloody effusion, or irritative factors in the pleural cavity may have accounted for an outpouring of first serum and then blood, particularly an embolus from a malignant tumor. Apparently, at one time at least, there was some degree of bronchial obstruction. If this was so, the obstruction may have been intrinsic, or due to a foreign body. I believe we can throw that out immediately because of the lack of a positive history. Or it may have been intrinsic tumor. Extrinsic pressure from a tumor mass, or intrinsic tumor, might well account for bronchial obstruction. The leukocytosis may have been on the basis of infection, although there was not the usual elevation of the

neutrophil count. Necrosis of tumor frequently causes elevation of the white-cell count.

This case is interesting to me because of the lack of respiratory symptoms, particularly cough. It is unusual to have obstruction of the bronchus, whether from intrinsic or extrinsic causes, not accompanied by cough. I should guess that the first respiratory distress occurred because of pressure of fluid on the lung. What diagnosis, therefore, can we entertain? In the first place, we can consider briefly, and let it drop promptly, the matter of vascular anomalies, such as congenital arteriovenous fistula. This probably should have been picked up by previous history and previous x-ray studies. These patients invariably have pathognomonic signs, and none were mentioned in the history or physical examination. We may think of parasites, such as the echinococcus, or fungi-like actinomycosis, but again we do not have fever or signs of irritation within the lung. The patient was apparently well until recently. I feel fairly confident in ruling out intrapulmonary tuberculosis because of the bloody pleural effusion.

Under the heading of tumors he may have had a primary bronchiogenic carcinoma. This patient was a young man, younger than the age group in which we usually find carcinoma of the lung, but it should be considered. Could he have had metastatic disease of the lung from some other source? Possibly. He had gastrointestinal symptoms, he may well have had gastric carcinoma. Again, he was young for that type of disease. Most likely of all the tumors, I believe, is sarcoma, because it occurs most frequently in the younger age groups. I believe that it is impossible to determine the nature of the sarcoma with the data at hand, but it may have been fibrosarcoma, it may also have been neurogenic fibrosarcoma or neuroblastoma. I do not believe that I can go farther than to say that he had a sarcoma.

We have, then, a young patient with a rapidly progressive disease characterized by pain, bloody pleural effusion and a lesion, which I believe was a malignant one, and the most likely diagnosis is sarcoma arising in the mediastinal tissues to produce pleural irritation and some degree of obstruction to the right main bronchus.

DR DONALD S KING We saw this man in the Thoracic Clinic and now that primary cancer of the pleura has been restored to good standing in

this hospital, we suggested that it might be that. That was one of the guesses raised at that time, — whether it was that type of growth. Lack of actual lung symptoms is one of the things that Dr. Miller has brought out that made us think of that possibility. Whether that would account for the tumor masses I do not know. I do not believe that we saw the films taken elsewhere, or if we did, I have forgotten.

DR. WYMAN: I am sorry we have not got them here to show you because, as I recall, the opinion of the X-ray Department was that the round masses described lay over the surface of the lung and along the parietal pleura. They were areas of round density, and we could not be sure that they were within the lung itself.

DR. KING: It sounds as if they were "consistent with the pleura."

#### CLINICAL DIAGNOSIS

Pleural endothelioma

DR. MILLER'S DIAGNOSIS

Sarcoma (of pleura or retropleural tissues)

#### ANATOMICAL DIAGNOSES

*Malignant teratoma of anterior mediastinum, involving pericardium, pleura and right lung*

*Hydrohemothorax, right.*

*Hydrohemothorax*

*Ascites*

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The operation mentioned at the termination of the history was a thoracoscopy. Examination of the aspirated fluid failed to show tumor cells, so that a thoracoscopy was done and a biopsy taken.

DR. JOHN G. SCANNELL: Two or three liters of bloody fluid was removed from the chest, and on inserting the thoracoscope one could see many raised, nodular, soft and purplish-blue areas on the parietal and visceral pleura. A biopsy was

taken. The lung could not be seen because there was so much bloody effusion, and the visceral pleura could not be identified.

DR. MALLORY: The biopsy specimen that Dr. Scannell provided us with showed a very undifferentiated tumor of relatively small cells, and we were finally persuaded to call it a mesothelioma. I know from long years of experience that that is a diagnosis one should never make and we were wrong once again. We have only 1 case in this hospital that I think may be a mesothelioma, and this is not it.

DR. KING: That is the one you burned me with once before.\*

DR. EDWARD D. CHURCHILL: Did the patient have x-ray treatment?

DR. MALLORY: Yes — quite a long course, with essentially no effect. He went steadily downhill and died three or four months after he was seen.

At autopsy we found an extensive tumor within the thoracic cage, both visceral and parietal pleuras on the right were solid masses of tumor, a large mass of tumor lay in the pericardial sac, another mass had invaded the right lung, destroying most of it beyond recognition, and still another mass of tumor was present in the anterior mediastinum. The tumor for the most part was quite soft and hemorrhagic and grossly was not characteristic of anything in particular. Microscopically, however, the diagnosis was immediately obvious. It showed a wide variety of types of tumor tissue, including squamous cells in some areas, gland formation in other places, large areas of endothelial-like tissue, which resemble closely the original biopsy, and in others, sarcoma, so that it was very evident that we were dealing with a teratoma. Teratomas are not uncommon in the chest, starting in the anterior mediastinum, and I think in all probability that was the primary source of this tumor.

## THE ANNUAL MEETING

THE one hundred and sixty-seventh anniversary of the founding of the Massachusetts Medical Society will be observed at its annual meeting to be held at the Hotel Statler in Boston on May 25, 26 and 27, 1948. The attendance should exceed by a considerable number that of a year ago, when 1521 physicians registered. As has been the case since the program was expanded to occupy three entire days, the meetings of the supervising censors and of the Council will be held on the preceding day, May 24. The entire program is published elsewhere in this issue of the *Journal*.

The general scientific sessions, of which six have been arranged, will be held each morning and afternoon at 9 00 a.m. and 2 00 p.m. A variety of topics will be covered, including medical aspects of the atomic bomb, nuclear fission and its application to medicine, a symposium on diseases of the liver and government propaganda and socialized medicine.

After the annual meeting, to be held at 11 00 a.m. on Tuesday, May 25, the annual oration, "The Responsibility of Medicine in the Propagation of Poor Protoplasm," will be delivered by Dr. Allen S. Johnson, visiting physician to the Springfield Hospital. Following the precedent established last year by Dr. O'Hara, then president of the Society, the 18 members still in active practice who joined the society in 1898 will be presented at this meeting and will be the guests of the Society at the annual luncheon.

On the evening of May 25 the Shattuck Lecture, "Surgery in the Aged," will be delivered by Dr. C. Stuart Welch, professor of surgery at Tufts College Medical School and surgeon-in-chief of the Joseph H. Pratt Diagnostic Hospital and the Boston Dispensary. The seven scientific sections of the Society will hold their luncheon meetings at noon on May 26 and 27.

On Wednesday, May 26, after a preprandial course in the interests of social adjustment the members of the Society and their wives will assemble for the annual dinner at 7 00 p.m. The speaker of the evening will be Mary Ellen Chase, Ph.D., professor of English Language and Literature at Smith College. Her subject will be "The Country Doctor on the Maine Coast."

A special program has been prepared for the wives of fellows attending the meeting. On Tuesday, May 25, they will be taken on a bus tour through historic Cambridge, not neglecting the glass flowers, to equally historic Concord, and then on to Wayside Inn for lunch. A Pops concert has been arranged for that evening, and on the following afternoon a tea and fashion show will be given at Filene's.

The men's annual golf tournament is scheduled for the afternoon of Wednesday, May 26, at the Woodland Golf Club.

Not only are all fellows of the Society urged to attend the various sessions of the annual meeting they are urged also to visit the scientific exhibits, this year increased to fifteen in number, and the eighty-three technical exhibits, not the least of which are to be found in the balconies

### THE CUTTER LECTURE

It is often difficult to administer an endowed lectureship without modifying or losing altogether the original purposes that motivated the donor. Such loss of purpose is frequently glossed over by a statement of progress, which calls attention to the fact that times have changed, times do change but not so fast or as much as is generally implied by these subterfuges. It is therefore refreshing either to hear or to read a lecture like that of Dr Haven Emerson, published elsewhere in this issue of the *Journal*.

Here speaks a man whose career has led him down the middle of the road. Beside this road, throughout his lifetime, there have bloomed attractive wayside flowers with which he might have dallied, and there have been on either side inviting woodsy carpaths where he surely could have strayed and escaped from it all. If he had done so, however, he could not have written this lecture; he would have been a specialist in some subdivision of public health instead of its "general practitioner."

In addition to his qualifications to speak, this lecturer has expressed himself in graceful and at times lofty language. Just as he has effectively quoted Abraham Lincoln and Henry I. Bowditch, so too may future lecturers turn and glean from him incisive statements of our current views—our facts, freedoms and formulas, as well as our fears, frustrations and follies. Our present era may well be looked back upon as a period in which every "subway mole knows the news of good health often before his own physician has been convinced of its authenticity," or in which "daily bulletins come to the press from the hirelings of philanthropy instead of from responsible health officers."

In another vein the lecturer says "we could almost rest upon the record for a spell if some miracle of nice human relations brought us freedom from sneezes as the sanitary privy, clean water and pasteurized milk have spared us from most of the diarrheas and enteritides." Looking into the future "The very logic and economy of leaving the water of milk at the point of production and replacing it where the milk is consumed will force health departments to permit sale of reconstituted milk and to protect the consumer against its commercial abuse. The largest undertaking of the future, and perhaps the most important in the opinion of the lecturer, is the sanitation of occupations. The opportunity of health protection appears to me at least as promising in this area as in the two large fields of nutritional and communicable diseases." The sociologist also comes to the surface "There is no future of promise in any public service that permits or encourages a shift of responsibility for children from the home and the parents into schools and health agencies of government." The modern version of Matthew (5:45) appears in the discussion of today's poliomyelitis extravaganza when reference is made to 'the zooming airplanes that sprinkle death-dealing dust on house flies and honey bees alike.'

This Cutter Lecture contains much more that is quotable and thought-provoking; it is commended to our readers.

### WORLD HEALTH REPUDIATED

The failure of Congress to ratify the World Health Organization of the United Nations is reminiscent of its attitude in the last century toward the International Red Cross. At that time the United States and Russia, year after year, were the only major powers that turned thumbs down on one of the greatest humanitarian movements that the world has ever known.

The United States then was through with conflict. It had just fought a civil war and was never again going to resort to arms. It did not need the

Red Cross, nor was it going to become involved in entangling alliances

In the present instance the Senate has approved participation, and the House Foreign Affairs Committee has given its unanimous approval, it is the House Rules Committee that has tabled the legislation without an explanation

Two more ratifications were necessary to secure the twenty-six votes needed to make the World Health Organization a full-fledged agency of the United Nations. These have been obtained, but without the leadership of the United States the representation of the western hemisphere will scarcely count. A democracy can at least lead the world in blowing hot and cold with the same breath

## RED CROSS AND THE BLOOD BANKS

ATTENTION is directed to a letter published elsewhere in this issue of the *Journal* from Dr Lamar Soutter and Dr Charles P. Emerson, Jr, directors respectively of the blood banks of the Massachusetts General and the Massachusetts Memorial hospitals. If, as expressed in this communication, efforts are being made to interfere with the fullest development of the Red Cross blood-collection program, not only is the health of the public being put in jeopardy, but national security itself may be threatened

Any program may justly be subject to constructive criticism, the only serious opposition to this particular enterprise comes from organizations that may have cause to fear its competition. These consist largely of local hospital banks, and, as Dr Soutter and Dr Emerson state, the hospital banks that they direct have been helped rather than injured by the Massachusetts State bank that has been in existence for two years and will now turn over its functions to the Red Cross

It is an ambitious program for a time of peace on which the Red Cross has embarked. No one can guarantee or as yet predict its success. The Red Cross, nevertheless, is our accepted national agency

for relief in time of distress, local or widespread, and this blood program may logically be construed as falling within its legitimate field of activity. It is the obligation of every citizen, lay or medical, to support it to the limit of its needs

## MEDICOLEGAL ABSTRACT

**Regulation of Professional Conduct—Effect of acquittal in criminal case on board's suspension order** In Massachusetts the professions are regulated by one inclusive statute (G. L. [Ter. Ed.] C. 112), which provides for an administrative board empowered to revoke and cancel the certificate and registration of anyone found "guilty of deceit, malpractice, gross misconduct in the practice of his profession, or of any offense against the laws of the commonwealth relating thereto." In the event that a doctor is found "not guilty" by a jury in a criminal proceeding, or "not negligent" in a civil proceeding, is such a finding binding on the board that was not a party in the proceeding? If a doctor commits some offense other than one in the practice of his profession, is he liable to be suspended under the terms of the statute? A recent case involved both problems.

The Board of Dental Examiners revoked the certificate of a dentist and canceled his registration on the ground that in his application for registration he had falsely and with intent to deceive claimed to be a graduate of Montreal College of Dentistry. In a subsequent criminal proceeding under the criminal provisions of C. 112, s. 52, he was tried and acquitted by a jury of the charge of falsely and with intent to deceive claiming to be a graduate of a college granting degrees in dentistry. Fifteen years later he petitioned the Supreme Judicial Court for reversal of the revocation, and his petition was dismissed by a single justice since "for aught that appears there may have been ample evidence before the board in 1932 indicating that the diploma" presented by the petitioner was a forgery.

On appeal the decision was affirmed, for the court construed the term "any offense" to cover not only "misconduct as a dentist" but also "the violation of any law relating to the practice of the profession of dentistry" including laws "relating to admission to that profession." Of the acquittal the court said:

That fact, in our opinion, does not vitiate the action of the board, for one reason because that action preceded the acquittal in point of time. Furthermore, this is a civil proceeding, while the acquittal was in a criminal proceeding, and the parties to the two proceedings are different.

(*Giroux v. Board of Dental Examiners*, 76 N. E. [2d] 758, 1948)

## MASSACHUSETTS MEDICAL SOCIETY

## DEATH

LAMBERT — Frederick D. Lambert M.D. of Tyngsboro died on April 20. He was in his seventy-first year.

Dr. Lambert received his degree from Boston University School of Medicine in 1900 and from Harvard Medical School in 1901. He was a former president of Middlesex North District Medical Society and had been a member of the Council of the Massachusetts Medical Society since 1927.

His widow, four sons, two brothers and eight grandchildren survive.

†Six year median.

## COMMENT

Diseases with incidence above the seven-year median are chicken pox, diphtheria, bacillary dysentery, measles and mumps.

Diseases with incidence below the seven-year median are German measles, lobar pneumonia, salmonellosis, scarlet fever, typhoid fever, undulant fever and whooping cough.

Diphtheria is declining but the number of cases is still higher than in eight out of the ten previous years. Lobar pneumonia is at the lowest level ever reported. Scarlet fever is at the lowest prevalence, except for three years, since 1918, and whooping cough continues to make new low records.

Only twice in the past has the number of cases of chicken pox exceeded the number reported in March of this year. Measles is at the highest prevalence since 1943, and mumps at the highest since 1945.

## GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Boston 11; Brockton, 1; Dedham 1; Duxbury 1; Malden 1; Medford 1; Quincy, 1; Revere 3; Somerville, 1; total 21.

Dysentery bacillary, was reported from Boston, 1; Marblehead 2; Melrose 1; Worcester, 5; total, 9.

Encephalitis, infectious was reported from: Lexington, 1; North Attleboro, 1; Somerville 1; Worcester 1, total, 4.

Malaria was reported from Amherst, 1; Ludlow, 1; Medford 3; Saugus, 1; Stoneham, 1; total 7.

Meningitis meningococcal was reported from Boston 2, Fitchburg, 1, Newton, 1; Pittsfield 1; Quincy, 1; total, 6.

Meningitis Pfeiffer bacillus, was reported from Amherst, 1; Everett, 1; total 2.

Meningitis, pneumococcal was reported from Holden, 1; Holyoke 1, total, 2.

Meningitis, streptococcal, was reported from Lowell, 1, total, 1.

Meningitis undetermined, was reported from Arlington, 1; Franklin, 1; Revere 1; Springfield 1; Templeton 2; Winchendon 1; Worcester 1; total 8.

Salmonellosis was reported from Auburn 1; Falmouth 1; Somerville, 1; Worcester 1; total 4.

Scarlet fever was reported from Boston 4; Everett, 1; total, 5.

Tetanus was reported from Cambridge 3; Danvers 2; Fall River 1; Medford 1; Somerville 1; total 8.

Typhoid fever was reported from Fall River 1; total, 1.

Undulant fever was reported from Acton 1; Bridgewater 1; Dudley, 1; Medway 1; total, 4.

LABORATORIES APPROVED FOR  
PREMARITAL AND PRENATAL  
BLOOD TESTS

The annual evaluation of the performance of laboratories doing diagnostic and serologic tests for syphilis has been completed. The laboratories now on the list approved for premarital and prenatal blood tests are as follows:

LOCATION	LABORATORY
Boston	Boston Dispensary
	Boston Health Department
	Commonwealth Clinical Laboratory
	Leary Laboratory
	Massachusetts General Hospital
	Massachusetts Memorial Hospitals (G. I. D. Clinic)
	State Wassermann Laboratory
	Brockton Health Department
	Sias Laboratory (Brooks Hospital)
	Clinton Hospital
Brockton	Union Hospital
	Barbank Hospital
	Fairview Hospital
	Holyoke Hospital
	Providence Hospital
Lowell	Lowell General Hospital
	Farren Memorial Hospital
	Clinical Laboratory
	St. Luke's Hospital
	Newton Wellesley Hospital
Newton	North Adams Hospital
	St. Luke's Hospital
	House of Mercy Hospital
	Salem Hospital
	Mersey Hospital
Springfield	State Infirmary and Hospital
	Noble Hospital
	St. Vincent Hospital
	Worcester City Hospital
	Worcester Health Department

## OFFICERS OF THE MASSACHUSETTS MEDICAL SOCIETY, 1947-1948

Bachrach

DR. DANIEL B REARDON, *President-Elect*

# PROGRAM OF THE ONE HUNDRED AND SIXTY-SEVENTH ANNIVERSARY OF THE MASSACHUSETTS MEDICAL SOCIETY

Monday, Tuesday, Wednesday and Thursday, May 24, 25, 26 and 27, Hotel Statler, Boston

The Registration Desk will be located on the Mezzanine Floor, and all who attend the meeting are requested to register

## MONDAY AFTERNOON MAY 24

- 4:00 Committee on Membership (PARLOR C)
- 4:30 Supervising Censors Meeting (PARLOR C)
- 6:00 Cotting Supper for Councilors (PARLORS A AND B)

9:30 *Treatment of the Anemias* DR. WILLIAM DAMESHEK, Boston Professor of clinical medicine, Tufts College Medical School hematologist, Joseph H Pratt Diagnostic Hospital

9:55 *The Relationship between the Industrial Physician and the Family Doctor* DR. THOMAS L. SHIPMAN, Manchester Instructor in industrial medicine, Harvard School of Public Health consultant in industrial medicine Salem Hospital clinical

Blackstone

DR. EDWARD P. BAGG, President

Art of Brown

DR. CHARLES J. KICKHAM, Past President

## MONDAY EVENING MAY 24

- 7:00 Annual Meeting of the Council (GEORGIAN ROOM)

## TUESDAY MORNING MAY 25

### First General Session

#### GEORGIAN ROOM

- DR. DWIGHT O'HARA Chairman
- DR. FREDERICK S. HOPKINS Co-chairman

- 9:05 A Motion Picture Entitled *Purposeful Splinting Following Injuries to the Hand* With a discussion by DR. SUMNER L. KOCH, MICHAEL L. VASON AND HARVEY S. ALLEN

assistant in medicine Massachusetts General Hospital

- 10:20 *Medical Aspects of the Atomic Bomb* DR. SNIELDS WARREN Boston Director division of biology and medicine, Atomic Energy Commission pathologist, New England Deaconess Hospital New England Baptist Hospital and Pondville State Hospital for Cancer

- 11:00 Annual Meeting of the Massachusetts Medical Society (GEORGIAN ROOM)

Annual Oration (following annual meeting) The Responsibility of Medicine in the Propagation of Poor Protoplasm DR. ALLEN S. JOHNSON Springfield Visiting physician Springfield Hospital

## THURSDAY AFTERNOON, MAY 27

## Sixth General Session

## GEORGIAN ROOM

DR. JOHN FALLON, *Chairman*DR. GEORGE S. REYNOLDS, *Co-chairman*

- 2 00 *Rubella and Congenital Defects* DR. CONRAD WESSELHOEFT, Boston Clinical professor of infectious diseases Harvard School of Public Health
- 2 25 *Endometriosis* DR. INGLIS F. FROST, New York City Chief of Endocrine Clinic, Women's Hospital
- 2 50 *Cutaneous Malignancies and Nevi* DR. EUGENE F. TRAUB, New York City Professor of dermatology, University of Vermont College of Medicine, formerly, clinical professor of dermatology and syphilology, New York Post-Graduate Hospital, Columbia University
- 3 15 *The Practical Importance of the Rh Factor* DR. LOUIS K. DIAMOND, Boston Assistant professor of pediatrics, Harvard Medical School, visiting physician, Children's Hospital, director, Blood Grouping Laboratory
- 3 40 *The Management of Surgical Pain* DR. EMERY A. ROVENSTINE, New York City Professor of anesthesia, New York University College of Medicine, director, Department of Anesthesiology, Bellevue Hospital
- 4 05 *Government Propaganda and Socialized Medicine* HON. FORREST A. HARNESS, member of Congress, Fifth District, Indiana
- 4 30 *Unexpected Death of Persons Not Suffering from Recognizable Disease* DR. ALAN R. MORITZ, Boston Professor of legal medicine, Harvard Medical School, pathologist-in-chief, Peter Bent Brigham Hospital

## SCIENTIFIC EXHIBITS

## BOOTH

- 81 — SPINDLE-CELL TUMORS OF THE GASTROINTESTINAL TRACT  
Sponsor Department of Roentgenology, Massachusetts General Hospital  
Exhibitors Dr. William L. Pallazzo and Dr. Milford S. Schulz  
METHODS OF REDUCTION AND FIXATION FOR FRACTURES OF THE JAW  
Sponsor Massachusetts General Hospital  
Exhibitor Dr. Kurt Thoma
- 82 — EPILEPSY ETIOLOGY AND TREATMENT  
Sponsor The Seizure Unit, The Children's Medical Center  
Exhibitors Dr. William G. Lennox and associates
- 83 — CORONARY HEART DISEASE  
Sponsor Departments of Medical Research and Pathology, Beth Israel Hospital  
Exhibitors Dr. Monroe J. Schlesinger, Dr. Herrman L. Blumgart and Dr. Paul M. Zoll  
PERITONEAL IRRIGATION FOR THE TREATMENT OF ACUTE RENAL FAILURE  
Sponsor The Surgical Department, Beth Israel Hospital

Exhibitors Dr. Howard A. Frank, Dr. Jacob Fine and Dr. Arnold M. Seligman

- 84 — PHOTOGRAPHIC EXHIBIT OF ACTIVITIES IN A FORMULA ROOM  
Sponsor Boston Lying-in Hospital
- 85 — VENOUS CATHETERIZATION OF THE HEART  
Sponsor Peter Bent Brigham Hospital  
Exhibitors Dr. Lewis Dexter and Dr. Merrill C. Sosman
- 86 — A DIRECT TEST FOR THE STUDY OF ASTHMA.  
Sponsor Allergy Clinic of the Evans Memorial and the Massachusetts Memorial Hospitals  
Exhibitors Dr. Francis C. Lowell and Dr. Irving W. Schiller
- 87 — DETECTION OF RADIOACTIVE MATERIAL.  
Sponsor Laboratory of Pathology and Radiation Department, New England Deaconess Hospital  
Exhibitors Russell F. Cowing and Charles K. Spalding  
PATHOLOGY OF RESECTED LUNGS  
Sponsor Laboratory of Pathology and Thoracic Service, New England Deaconess Hospital  
Exhibitors Dr. Richard H. Overholt and Dr. William A. Meissner
- 88 — POLYPS OF THE COLON AND RECTUM  
Sponsor Lahey Clinic  
Exhibitors Dr. Richard B. Cattell and Dr. Neil W. Swinton
- 89 — CARCINOMA IN SITU OF THE CERVIX AND ENDOMETRIUM  
Sponsor Free Hospital for Women  
Exhibitors Dr. Paul A. Younge and Dr. Arthur T. Hertig
- 90 — RHEUMATOID ARTHRITIS, ITS MEDICAL AND ORTHOPEDIC CARE.  
Sponsor Robert B. Brigham Hospital  
Exhibitors Dr. Theodore B. Bayles and Dr. Theodore A. Potter and associates
- 91 — REPAIR OF CLEFT LIPS  
Sponsor Plastic Division of the Department of Surgery, The Children's Hospital  
Exhibitor Dr. Donald W. MacCollum
- BALCONY
- 203 — HEART DISEASE IN THE PRODUCTIVE AGES — FOREMOST PUBLIC-HEALTH CHALLENGE  
Sponsor Massachusetts Heart Disease Study of the Massachusetts Department of Public Health, Harvard Medical School and the United States Public Health Service  
Exhibitors Dr. Vlado A. Getting, Dr. Lewis C. Robbins and Dr. Gilcin F. Meadors
- 206 — UROLOGICAL CASE STUDIES  
Sponsor Urological Department, Mount Auburn Hospital and Department of Surgery, Tufts College Medical School  
Exhibitors Dr. Harold A. Chamberlin and Dr. Joseph Fischmann

## ANNUAL GOLF TOURNAMENT

WOODLAND GOLF CLUB

NEWTON MASSACHUSETTS

WEDNESDAY AFTERNOON, MAY 26

1:00 p. m.

DR. HENRY W. GODFREY, Newton, Chairman

## MISCELLANY

## BRISTOL NORTH DISTRICT MEDICAL SOCIETY

At the annual meeting of the Bristol North District Medical Society held at the Taunton Inn on April 15 the need of communities being covered for medical emergencies was discussed. It was proposed that this problem be handled by individual cities and towns and that reports be presented at the next meeting.

The establishment of a district women's auxiliary was approved.

Mr. Charles J. Dunn discussed malpractice from the point of view of an attorney.

W. E. DAWSON Secretary

## MASSACHUSETTS TRUDEAU SOCIETY

At the annual meeting of the Massachusetts Trudeau Society held in Boston on April 14, the following officers were elected to serve for the term of one year: president, Dr. Donald S. King; vice-president, Dr. Theodore L. Badger, and secretary-treasurer Dr. Edward J. Welch.

## CORRESPONDENCE

## RED CROSS BLOOD COLLECTION PROGRAM

To the Editor: Recently many of us in the field of blood banking have been greatly concerned by the efforts of certain persons to sabotage the Red Cross blood collection program.

We believe that doctors everywhere should realize the importance of the Red Cross effort both locally and nationally. If it succeeds it will mean free blood available in large quantities when needed; it will mean free blood in small hospital areas where heretofore transfusions were often impossible; and last but not least, it will mean an adequate mechanism for blood collection and distribution in case of enemy attack.

There is a fear by some that their blood banks will be engulfed by the Red Cross. In Massachusetts we have had an

excellent state bank in operation for two years, recently taken over by the Red Cross. We have been greatly assisted by this bank, not engulfed by it. The Red Cross intends to maintain this bank's high standards, and has avowed that there will be no interference with established banks. The criticism has been made that the Red Cross program is a step toward socialized medicine. Do those who make this statement realize that, in case of war, if there is no voluntary organization of this sort to collect and distribute blood, the government will establish its own banking system? Lastly, certain persons have stated that the Red Cross program cannot succeed. We do not know whether it can or not, but we do know that it has made a good beginning and that the benefits to be derived in the care of patients make it worth while for all of us to give it our unqualified support. With that backing, its chances of being successful should be greatly enhanced.

LAMAR SOUTTER

Director of Blood Bank  
Massachusetts General Hospital

CHARLES P. EMERSON, JR.

Director of Blood Bank  
Massachusetts Memorial Hospitals

## MORE ON WHITE CROSS

Dr Channing Frothingham's letter, published in the *Journal* of May 6, was referred to Dr Elmer S. Bagnall, whose comments are as follows:

*To the Editor:* The first paragraph of Dr Frothingham's letter states that this is the first request from a representative of the Massachusetts Medical Society for information about White Cross. On the contrary, as president-elect of the Massachusetts Medical Society, I made identical suggestions at the Twentieth Century Club, on March 8, 1945, with Dr Allan M. Butler and Dr Nathaniel W. Faxon participating and the present Governor Bradford presiding.

The president of the Massachusetts Medical Society in 1939 was Dr Channing Frothingham. If, as the ex-officio chairman of the Public Relations Committee, he does not seem to recall now the sequence of facts, the records of that committee, which then handled all these matters for the Society, will substantiate my statements. I was secretary of the Public Relations Committee at that time.

I have known and liked Dr Frothingham since our days together at Camp Devens. I recall vividly how energetically we of the committee discussed the plans that were later known as the Blue Shield and the White Cross, as well as other proposals. I remember too that enabling legislation for both these plans was adopted almost simultaneously. So far as Dr Frothingham's attitude was concerned, I stand by the statement quoted from my article.

Subsequent discussion in the letter suggests that I had untruthful motives. Those of you who know me, know better. Perhaps I did not make it clear enough that such experimental plans as the White Cross could illuminate the path of those carrying responsibility for plans now operating so that they would not repeat misjudgments in purpose or timing. The Blue Shield carries on but needs to be constantly cautious in its evolution. As a director of Blue Cross I can say that more and better use of available information about rough roads by all concerned would have saved us recent unhappy experiences. It is unfortunate that there are too many people in this country who would welcome failure of the Blue Cross and Blue Shield plans.

Also, I want to state with proper emphasis that although the Massachusetts Medical Society did not endorse and adopt the White Cross as its own, the next president, Dr Walter Phippen, and the Society leaned backward not even to seem to be critical of it. The records of the Public Relations Committee will support this statement. I was still its secretary and well remember that some White Cross press reports seemed to want the public to believe the contrary.

Finally, if the White Cross plan was so well adapted to the needs of the people and met its demise only from the depletion of its ranks with war, I hope that now it will be resumed and contribute to everyone's objective — better medical care for more people.

ELMER S. BAGNALL, M.D.

281 Main Street  
Groveland, Massachusetts

## BOOK REVIEWS

*Aphasia: A guide of retraining.* By Captain Louis Granch, with an appendix in collaboration with Sergeant George W. Pangle. 8°, cloth, 108 pp. New York: Grune and Stratton, 1946. \$2.75.

During the war cerebral injury gave rise to a considerable number of patients who were handicapped by speech defects, particularly aphasia, but were otherwise in good health. The matter was given consideration by the United States Army Medical Corps as early as April, 1945, and a technical bulletin was issued. The author has had practical experience in training aphasic patients at one of the large hospitals established in this country. He based his work largely on the previous investigations of J. M. Nielsen and Kurt Goldstein. In his brief manual he gives the basic findings in cases of dysarthria, including aphasia, and outlines a method of rehabilitation that he has found successful. The book is of value particularly as it gives in some detail actual experiences in handling patients with this type of disability.

*Communal Sick-Care in the German Ghetto.* By Jacob R. Marcus, Ph.D., and Adolph S. Ochs, Professor of Jewish History, Hebrew Union College. 8°, cloth, 335 pp. Cincinnati: The Hebrew Union College Press, 1947. \$2.50.

The author presents a detailed study of Jewish communal care — the action of the Jewish community and its accredited agencies — in providing medical services in the German lands of the late medieval period. The region covered is roughly the Holy Roman Empire — primarily, Germany and the Hapsburg lands. However, frequent reference is made to Polish and even to English institutions, since the German or Ashkenazic rite was found or prevailed in these areas. No attempt has been made to investigate the Sephardic or Spanish-Jewish institutions in North Germany, Holland and England. The term "medieval" as used in this work refers to the period from about 1500 to 1800. The term "ghetto" is used in its broadest sense as a synonym for the Jewish quarter — the self-contained, legally recognized Jewish community of the sixteenth to the nineteenth century.

The work is divided into a number of chapters. The first discusses direct communal care of the sick. Then follow chapters on the origin, structure and operation of the *Hebra Kaddisha* (Holy Brotherhood), women's societies for the care of the sick, Jewish youth movements in Europe in the eighteenth century, the *Hekdesh* or Jewish hospital and the beginnings of the modern Jewish hospital. A number of appendixes contain reproductions of early documents and historical material supplemental to the text. A good index concludes the volume.

The material is well organized. The volume is a credit to the printers. The publishing is excellent. A good large type on soft, light paper makes reading a pleasure. This scholarly work should be in all history collections, medical and general.

*Office Treatment of the Eye.* By Elias Selinger, M.D. 8°, cloth, 542 pp., with 67 illustrations. Chicago: The Year-Book Publishers, Incorporated, 1947. \$7.75.

This well written volume contains 67 illustrations and 526 pages of text arranged in sixteen chapters, grouped under chemotherapy, foreign bodies, ocular injuries, refraction, ocular muscles, lacrimal apparatus, orbit, eyelids, conjunctiva, cornea, sclera, lens and vitreous, glaucoma, uveal tract, retina, optic nerve and appendix.

The author recognizes the wide latitude of opinion about the efficacy of therapy, and he draws upon 160 cited authorities, as well as his own clinical experience, to set down helpful suggestions for the reader. The book deserves a place on the shelf of the practitioner, whether he be a general practitioner or ophthalmologist, because it makes accessible the therapeutic measures of proved worth of yesterday, as well as the promising measures of today.

The work lends itself to minor criticism from the point of view of the ophthalmologist. Since more than half the procedures recommended by the author require hospitalization, the title of the book should omit the word "office," and thus be contracted to "Treatment of the Eye." The first and most prominent chapter is devoted to chemotherapy, which appears again and again in subsequent chap-

ters of the book. Although chemotherapy has its indications, it also has its contraindications and one must be wise in selecting the therapeutic agent in terms of greatest efficiency and least hazard. The author's statement in his preface, as well as his method of approach in the text itself implies that he is trying to steer a middle course—to serve the general practitioner and the ophthalmologist alike. To serve the former the text would have to teach anatomy, physiology, pathology, pharmacology and clinical diagnosis before considering therapeutics. The truth is that skill in diagnosis and treatment cannot be vicariously obtained but that it is the reward won by penetrating contacts with patients over the years.

*Dr Kirkbride and his Mental Hospital.* By Earl D. Bond M.D. 8 cloth 163 pp. with 7 illustrations. Philadelphia J. B. Lippincott Company 1947 \$3.50.

This book is a biography of Dr. Kirkbride and a history of the Pennsylvania Hospital for the Insane. The first part is devoted to the early life of the doctor, who was born in 1809 and died in 1883; his early education at Quaker schools, his medical years at the University of Pennsylvania, his years of early practice and his turn to psychiatry in 1840. The second part concerns the history of the hospital in its original building from 1841-1859 and in the second building finished in 1859. Dr. Kirkbride designed the second building after ideas original to him. At least thirty-one states built hospitals on his plan. He embodied his ideas and observations on the care of the insane in a book entitled *Hospitals for the Insane*, published in Philadelphia in 1854 and 1880 by the J. B. Lippincott Company. The doctor's life was filled with trials and tribulations because of his advanced ideas but he weathered all attacks. The hospital was never his chief concern; he was more interested in the patient as an individual. The biography is written in a easy, narrative style. It is well published and should be in all medical history collections.

*Diagnosis in Daily Practice. An office routine based on the incidence of various diseases.* By Benjamin V. White M.D. and Charles F. Geschickter M.D. 8 cloth 693 pp. with 360 illustrations and 104 tables. Philadelphia J. B. Lippincott Company, 1947 \$15.00.

An internist and a pathologist, happily teamed, have pooled their teaching experience to producing this well integrated work on diagnosis in daily practice. It is a good book—somewhat heavy in style but in several respects novel in approach and organization. The volume is extraordinarily compact even in the facing pages in the front and at the end are utilized. In the former there is a list of the major causes of death and disability in the United States prepared from the vital statistics of the Census Bureau and the National Health Survey so as "to bring them to the medical consciousness." In the latter there is a list of major abnormalities to be sought on routine examination together with supplementary procedures to be undertaken in the presence of routine findings and with references to the pages in which they are discussed.

The authors stress greatly what they term "presymptomatic medicine." It lies midway between preventive and therapeutic medicine, aimed at the recognition of abnormalities of structure or function which may be the basis of subsequent disability or disease and which may be only in incipient to the examination for a current illness or to a periodic health examination. Thus the physician examines the patient for a respiratory disease may discover some precancerous lesion of the skin. This phase of medicine has been made possible by newly acquired knowledge of the precursors or early stages of disease whose association with the fully developed forms was not previously recognized.

The book is richly illustrated by 360 unusually enlightening diagrams, tables and photographs in black and white and in color in a total of 700 pages. This is a notable pedagogic contribution. Many of the illustrations are credited to the Massachusetts General Hospital.

There are five parts: the diagnostic survey including a section on statistical methods; diagnosis of abnormal symptoms; diagnosis of abnormal physical findings; laboratory procedures and major diseases. The last part, which is exhaustive, considers diseases of the secretory organs of the

female reproductive organs and of the peripheral vascular and central nervous systems and the psychoses. There is even a section on the final one, on office arrangement and equipment, which the authors hold may influence the character of the physician's work.

On the whole this is a worth while reference work for the advanced student and the practitioner.

The increasing practice of printing important material on the lining papers of the binding of a volume cannot be too severely criticized. The papers become defaced and soiled from use and are lost in rebinding.

*The Practical Nurse.* By Dorothy Deming R.N. 8 cloth 370 pp. New York The Commonwealth Fund, 1947 \$3.00.

This is not a textbook of practical nursing but a comprehensive treatise on the need, usefulness and supervision of practical nurses in the home, in general and special hospitals, in industry and public health and in federal institutions. There are special chapters on training, supervision and legislation. To each chapter is appended a list of references for further reading. The appendixes include lists of textbooks and instruction outlines, approved schools of practical nursing (ten in Massachusetts, the second largest number in the country), and opinions concerning state licensure of practical nurses. The author believes that there is a need and future for the practical nurse but that there should be mandatory legislation to protect the public and the nursing profession. A definite long range plan is formulated for the training, utilization and protection of the practical nurse. The text is well written and the material well organized. The publication is excellent, well up to the high standard of the Commonwealth Fund. The volume is recommended for all medical and general libraries.

## BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*Emotional Maturity. The development and dynamics of personality.* By Leo J. Saul M.A. M.D. associate professor of psychiatry, Temple University School of Medicine and special lecturer in psychiatric information, Bryn Mawr College. 8 cloth 338 pp. Philadelphia J. B. Lippincott Company 1947 \$5.00.

*Amiable Autocrat. A biography of Dr. Oliver Wendell Holmes.* By Eleanor M. Tilton Ph.D. 8 cloth 470 pp. New York Henry Schuman 1947 \$5.00.

*Medicine.* By A. E. Clark Kennedy M.D. F.R.C.P. physician to the London Hospital and dean of the medical school. Volume 1. *The patient and his disease.* 8 cloth 383 pp. Baltimore: Williams and Wilkins Company, 1947 \$6.00.

*Sexual Behavior in the Human Male.* By Alfred C. Kinsey, Sr. D. professor of zoology, Indiana University; Wardell B. Pomeroy, research associate, Indiana University; and Clyde E. Martin, research associate, Indiana University. 8 cloth 805 pp. with 173 illustrations and 162 tables. Philadelphia W. B. Saunders Company 1948 \$6.50.

*Psychopathology and Education of the Brain Injured Child.* By Alfred A. Strauss, psychoeducational consultant, Evanston, Illinois; and president, Cove Schools for Brain Injured Children, Racine, Wisconsin; and Laura E. Lehtinen, psychoeducational consultant, Evanston, Illinois; and educational director, Cove Schools for Brain Injured Children, Racine, Wisconsin. 8 cloth, 206 pp. with 46 illustrations. New York: Grune and Stratton, 1947 \$5.00.

## NOTICES

## ANNOUNCEMENTS

Dr J Dellinger Barney announces the removal of his office to 412 Beacon Street, Boston

Drs M Leopold Brodny and Daniel Rosen announce the removal of their offices to 636 Beacon Street, Boston, for the practice of urology

## HARVARD MEDICAL SCHOOL CLASS OF 1898

The fiftieth anniversary reunion and dinner of the Harvard Medical School Class of 1898 will be held at the Harvard Club of Boston, 374 Commonwealth Avenue, Boston, on Friday, June 11, at 7 00 p m

Members of the Class who intend to be present should notify the Harvard Medical Alumni Office, Harvard Medical School

## SOUTH END MEDICAL CLUB

A meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, May 18, at 12 m

Dr Wyland F Leadbetter will speak on the subject "The Diagnosis and Treatment of Infections of the Genitourinary Tract."

Physicians are cordially invited to attend

## BOSTON GASTROENTEROLOGICAL SOCIETY

A meeting of the Boston Gastroenterological Society will be held in the New Cheever Amphitheater, of the Boston City Hospital, Dowling Building, Boston, at 12 noon on Wednesday, May 19 Dr Frank H Lahcy will speak on the subject "Carcinoma of the Large Bowel, Ulcerative Colitis and Terminal Ileitis"

## MASSACHUSETTS PHYSICIANS' ART ASSOCIATION

An exhibition of works of art by members of the Massachusetts Physicians' Art Association will be held in Room 409, Hotel Statler, throughout the annual meeting of the Massachusetts Medical Society, May 25 to 27, from 9 a m to 5 p m

## NEW ENGLAND HEART ASSOCIATION

The annual Henry Jackson Lecture, under the auspices of the New England Heart Association, will be given by Dr André Cournand, associate professor of medicine, College of Physicians and Surgeons, Columbia University, in the Boston Medical Library, Boston, at 8 15 p m on Monday, May 24 His subject will be "Recent Developments in the Study of the Pulmonary Circulation in Chronic Pulmonary Diseases"

A short business meeting will precede the lecture Interested physicians and medical students are invited to attend

## ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES

The annual meeting of the Association of Military Surgeons of the United States will be held in San Antonio, Texas, from November 10 to 13, and not in Atlantic City, New Jersey, on May 4 and 5, as previously announced in the *Journal*

## AMERICAN COLLEGE OF RADIOLOGY

The annual meeting of the American College of Radiology will be held at the Sberaton Hotel, Chicago, on Sunday, June 20 A dinner in honor of former presidents of the College and a commemoration of the fiftieth anniversary of the discovery of radium will be features of the meeting

## RESIDENCIES IN PSYCHIATRY

Residencies in psychiatry are available at the Veterans Administration Hospital, Roanoke, Virginia Training will be given at the hospital under the supervision of the Department of Psychiatry, University of Virginia School of Medicine A three-year program approved by the American Medical Association will include didactic and clinical instruction in all phases of psychiatry and basic neurology Residents will also actively participate in methods and techniques of treating psychiatric patients

Applications should be addressed to the manager, Veterans Administration Hospital, Roanoke 17, Virginia

## POSITIONS OPEN IN VETERANS ADMINISTRATION HOSPITALS

The Chief Medical Director of the Veterans Administration has recently announced a new program regarding specialty practice in Veterans Administration hospitals The program will apply to graduates who have completed three years of formal training at other institutions and wish to complete the qualifications of their specialty boards through supervised practice in their chosen specialties as full-time Veterans Administration employees This program has already been approved by the boards in medicine, surgery and neuropsychiatry

The present plan, which has been made possible by the termination of the appointments of some 1400 to 1500 ASTP and V12 physicians by July 1, applies particularly to hospitals that are not located in cities where teaching institutions are now connected with the Veterans Administration All the supervising consultants, however, will be connected with medical schools

This program appears to offer an unusual opportunity for young men to demonstrate their ability and to gain unusual experience in a chosen field Application should be made to the nearest Veterans Administration Branch Office These are to be found in the following cities Boston, New York City, Philadelphia, Richmond, Atlanta, Columbus, Chicago, St Paul, St Louis, Dallas, Seattle, San Francisco and Denver

## MEDICAL AND SURGICAL SUPPLIES FOR PALESTINE

Because of the extreme need for medical and surgical supplies for the care of wounded Jews in Palestine, the Greater Boston Medical Society is sponsoring a drive for the following articles surgical instruments of all types penicillin, streptomycin, syringes of all sizes, needles of all sizes, bandages, and gauze pads Cash contributions for the purchase of such supplies will also be welcomed, checks should be made payable to the Greater Boston Medical Society and mailed to Dr Bernard I Goldberg, 481 Beacon Street, Boston Any supplies contributed should be delivered to Dr Goldberg, to Dr David Davis, 416 Marlborough Street, Boston, or to the Brookline Hadassah Office, 251 Harvard Street (Room 7), Brookline

## SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MAY 20

THURSDAY, MAY 20

12 00 m Clinical Staff Meeting Nurses' Home, Allerton Hospital, Brookline

FRIDAY, MAY 21

\*9 00-10 00 a m Problems Relating to Bacterial Resistance. Dr Tom Fite Paine, Jr Joseph H Pratt Diagnostic Hospital  
\*10 00 a m-12 00 m Medical Staff Rounds Peter Bent Brigham Hospital

MONDAY, MAY 24

\*12 00 m Clinicopathological Conference. Margaret Jewett Hall Mt. Auburn Hospital, Cambridge  
\*8 15 p m New England Heart Association Boston Medical Library

(Notices concluded on page xvii)

NOTICES (Concluded from page 722)

TUESDAY MAY 25

- \*12:15-1:15 p.m. Clinico-radiogenetic Conference Peter Bent Brigham Hospital.
- \*1:30-2:30 p.m. Pediatric Rounds Burnham Memorial Hospital for Children Massachusetts General Hospital

WEDNESDAY MAY 26

- \*9:00-10:00 a.m. Non-Specific Urethritis. Dr. Lewis W. Kane Joseph H. Pratt Diagnostic Hospital
- \*12:00 m. Grand Rounds and Clinicopathological Conference (Children's Hospital.) Amphitheater Peter Bent Brigham Hospital
- \*2:00-3:00 p.m. Combined Clinic by the Medical Surgical and Orthopedic Services. Amphitheater Children's Hospital.

## PORTACAVAL SHUNTS IN THE TREATMENT OF PORTAL HYPERTENSION\*

With Special Reference to Patients Previously Operated Upon

ROBERT R. LINTON, MD†

BOSTON

A NEW chapter is being written on the treatment of portal hypertension with bleeding esophageal varices. Eck,<sup>1</sup> in 1877, was the first to demonstrate that the portal vein can be anastomosed to the inferior vena cava in animal experiments. From then until 1945 only a few sporadic attempts of portacaval shunts in human beings were reported in the literature. Most of these were unsuccessful, but with the recent favorable reports of Whipple<sup>2</sup> in 1945 and Blakemore<sup>3</sup> in 1945 and 1947, a renewed interest has been stimulated in this subject. These authors have described two types of venous shunts to reduce the portal hypertension: an end-to-end anastomosis between the splenic and left renal veins, after a splenectomy and a left nephrectomy have been performed, and an end-to-side anastomosis between the distal end of the divided portal vein and the inferior vena cava. As a result of accumulated experience in this new surgical field it has been found that it is not possible to utilize either type of venous anastomosis in every case. This is especially true in cases in which a previous splenectomy has been done in an attempt to control the portal hypertension and bleeding from the esophagogastrintestinal tract. Furthermore, it has seemed undesirable to remove a healthy organ, such as the left kidney, unless it is otherwise impossible to make a satisfactory shunt. Accordingly, an end-to-side anastomosis between the end of the splenic vein and the side of the renal vein without nephrectomy has been developed.<sup>4</sup>

The purpose of this paper is to report 4 cases of portal hypertension secondary to an extrahepatic portal bed block with continued esophagogastrintestinal bleeding despite previous surgical procedures. Three patients had had splenectomies, and the other multiple operations in an attempt to control the portal hypertension.

### CASE REPORTS

**CASE 1.** L. M. (M.G.H. 21,099), a 12-year-old boy, was admitted to the hospital on December 17, 1929, because of hematemesis. He had been admitted to the Children's Hospital, Boston, in 1925 and 1927 because of similar episodes. In that institution the bleeding had stopped spontaneously after a transfusion. The most recent episode of bleeding had begun 2 days before admission.

Physical examination revealed an enlarged spleen. A diagnosis of bleeding esophageal varices due to splenic vein obstruction (Banti's syndrome) was made. After appropriate preoperative care, a splenectomy by an abdominal approach was performed by Dr. Arthur W. Allen. The patient did well and was discharged on January 25, 1930.

He was readmitted on November 11, because of hematemesis. Operation was performed by Dr. Allen, who ligated numerous dilated veins in the gastrohepatic omentum and in the region of the left gastric vein. The patient was discharged on December 24 and was subsequently readmitted on January 15, 1931, for a tonsillectomy on April 23, 1932, because of hematemesis, on February 14, 1937, because of hematemesis and on January 15, 1944, because of hematemesis and for an esophagoscopy and injection of the varices with 5 per cent sodium morrhuate solution. Between January 8 and July 13, 1945, the patient was readmitted five times for esophagoscopy and injection of varices. He was well until September 22, when he vomited about 500 cc. of blood. He was readmitted for a portacaval anastomosis.

At operation on October 9, the superior mesenteric vein was isolated at the base of the mesentery of the small bowel. It was divided and the proximal end was anastomosed to the side of the inferior vena cava distal to the renal veins (Fig. 1). Biopsy showed a normal liver. The patient made a satisfactory recovery and was discharged from the hospital 15 days after the operation.

When seen on August 8, 1947, he had had no further esophagogastrintestinal bleeding and was working full time as a painter. A gastrointestinal series revealed no change in the esophageal varices. The hemoglobin was 13.9 gm. per 100 cc. and the white-cell count 9700.

**CASE 2.** F. L. (M.G.H. 333,628), a 16-year-old schoolgirl, was admitted to the hospital on December 25, 1941, because of a sudden hematemesis of 1 day's duration. Physical examination revealed an enlarged spleen two fingerbreadths below the costal margin. A roentgenogram of the esophagus showed large esophageal varices. Liver function tests were negative. A diagnosis of splenomegaly with esophageal varices (Banti's syndrome) was made. On January 19, 1942, a splenectomy and ligation of several large periesophageal varices were done through a transthoracic approach by Dr. Richard H. Sweet. The patient was discharged from the hospital on February 28.

She was seen occasionally in the Out Patient Department and Medical Clinic and was well without symptoms until April 11, 1946, when she was readmitted to the hospital because of hematemesis of 1 day's duration. She was dis-

\*Presented at the annual meeting of the New England Surgical Society, Providence, Rhode Island, October 3, 1947.

charged on May 3. The patient re-entered the hospital for a portacaval shunt on July 5. An operation on July 13 was performed through a transabdominal left subcostal incision. It was impossible to find the splenic vein, since its proximal end had become fibrosed and narrowed, and it was un-

FIGURE 1 Schematic Drawing, Showing the Anastomosis between the Proximal End of the Divided Superior Mesenteric Vein and the Side of the Inferior Vena Cava Distal to the Renal Veins

This type of shunt was used in Case 1, and since it was performed the patient has had no further esophagogastrintestinal bleeding for over twenty-two months

suitable for a venous anastomosis. The largest vein in the portal system that could be found was the inferior mesenteric vein, which was divided and the proximal end anastomosed to the left ovarian vein (Fig 2). The liver biopsy was

FIGURE 2 Schematic Drawing, Showing the Anastomosis between the Proximal End of the Divided Inferior Mesenteric Vein and the Side of the Left Ovarian Vein

It was necessary to sever the ovarian vein because of tension on the anastomosis. This type of shunt was used in Case 2, and since it was performed the patient has had no further esophagogastrintestinal bleeding for over fourteen months

reported as normal. The patient did well and was discharged from the hospital on July 30.

The patient has been seen several times in the Out Patient Department and she has had no symptoms. A repeat gastrointestinal series in June, 1947, revealed the esophageal varices to be unchanged. However, she has had no further bleeding in the 14 months since the operation.

CASE 3 J M (MGH 36), a 19-year-old male dental mechanic, was admitted to the hospital on November 6, 1935, because of tarry stools of 1 day's duration. Physical examination revealed that the liver and spleen were both slightly enlarged. A gastrointestinal x-ray series revealed extensive, large esophageal varices. A diagnosis of Banti's disease with bleeding esophageal varices was made. On December 5 the splenic artery was ligated in continuity with chromic catgut by Dr Beth Vincent, and an extensive intraperitoneal omentopexy was performed at the same operation. The patient did well and was discharged on December 20.

On January 2, 1937, he was readmitted because of hematemesis and tarry stools of 1 day's duration. He had repeated massive hematemeses on January 18, 19 and 20, requiring eight transfusions. He steadily improved, and a second operation was performed on February 3 by Dr Arthur W. Allen. Several large veins on the diaphragm along the lesser curvature of the stomach were ligated. The patient was discharged on March 2. He was readmitted on February 14, 1939, because of repeated tarry stools, and was discharged on March 17. He was subsequently admitted on April 28 and August 21, 1939, and February 7 and August 16, 1940,

FIGURE 3 Schematic Drawing, Showing the End-to-Side Splenorenal Anastomosis, with Preservation of the Left Kidney. This is the operation of choice in cases especially with a cavernomatous transformation of the portal vein, since a direct portacaval anastomosis cannot be performed in such patients. It should be performed at the same operative procedure as the splenectomy. This type of shunt was used in Case 3, and since it was performed the patient has had no further esophagogastrintestinal bleeding for over fourteen months.

because of melena. On October 31, 1940, he re-entered the hospital for esophagoscopy, being discharged on November 6. Because of melena he was again admitted on November 7, five esophagoscopies, with injection of varices, were performed, and he was discharged on December 23. Between re-entry on January 9 and discharge on February 6, 1941, four esophagoscopies, with injections, were performed. Another episode of melena caused him to be readmitted on February 13, esophagoscopy, with injection of varices, was performed, and he was discharged on March 13. He re-entered the hospital on April 14 because of melena, esophagoscopy was performed, and he was discharged on May 2. Between May 18 and November 14 he was admitted seven times for esophagoscopy and injection of esophageal varices. At the twentieth admission, on February 5, 1942, cannulation of an intercostal vein for phlebography was attempted, the patient being discharged the next day. Between June 17 and June 26 he was readmitted because of melena. On July 25 he re-entered the hospital for a transthoracic exposure of the esophagus and ligation of several large periesophageal veins, performed by Dr Richard H. Sweet, and was discharged on August 12. He was readmitted for 2 days on September 11 for esophagoscopy and for 9 days on November 5 because of melena. Between April 4 and May 13, 1943, he was readmitted because of hematemesis and melena. On June 14, 1943, March 17 and October 27, 1944, and March 3 and September 21, 1945, he re-entered the hospital

for esophagoscopy and injection of esophageal varices each admission lasting 2 days. He was readmitted on March 28, 1946, because of hematemesis, and esophagoscopy and injection of esophageal varices were performed, the patient being discharged on March 30. On April 6 he was hospitalized because of massive hematemesis of 1 day's duration. At operation on April 24 through a right abdominal incision the portal vein could not be exposed because of the extensive hemorrhage. In the dissection the common bile duct was accidentally transected, and the cystic duct was also injured. Accordingly, a cholecystectomy and a choledochojunostomy were performed the latter according to Allen's method. The patient made a slow but satisfactory recovery, being discharged on May 29. On June 6 he was readmitted for a final attempt at a portacaval shunt. At operation on June 8 the spleen was exposed through a left thoracoabdominal incision. It was removed with great difficulty owing to numerous vascular adhesions including many formed as a result of the omentopexies. Considerable blood was lost and the patient received 3000 cc. of citrated blood by transfusion from the blood bank and at least 3000 cc. of citrated blood by autotransfusion. An end-to-side suture anastomosis was accomplished between the splenic vein and the renal vein after the removal of the spleen (Fig. 3).<sup>\*</sup> The renal artery was occluded for 20 minutes during the construction of the anastomosis. The operation required 6½ hours and the patient was under anesthesia for 7 hours and 45 minutes. Oliguria developed on the day after operation persisting for several days. The blood nonprotein nitrogen gradually rose to 103 mg per 100 cc. on the 6th postoperative day and then gradually returned to normal. At discharge from the hospital on May 29 it was 18 mg per 100 cc., and the urine concentrated to 1,003.

The patient was last seen on August 8, 1947 when he felt well and had had no further bleeding episodes after the splenorenal anastomosis had been completed. The hemoglobin was 17 gm per 100 cc. and the white-cell count 10,000, the urine concentrated to a specific gravity of 1.022. The nonprotein nitrogen was 27 mg per 100 cc. The esophageal varices, however, appeared unchanged on x-ray examination.

**CASE 4.** M. M. (M.G.H. 434-339) a 19-year-old girl was admitted to the hospital on February 4, 1944, because of repeated episodes of hematemesis over a 5-year period. The last attack had begun 5 days before admission.

Physical examination revealed a large young woman in no acute distress. The abdomen was normal except that the spleen could be palpated three fingerbreadths below the costal margin. The liver was not enlarged. A roentgenologic examination of the gastrointestinal tract showed esophageal varices. A liver biopsy specimen obtained by percutaneous biopsy was reported as showing a normal liver. A diagnosis of Bant's syndrome was made. On March 9 a splenectomy was performed through a transthoracic approach by Dr. Richard H. Sweet. The splenic vein was noted to be about 2 cm in diameter. In addition several large periesophageal veins and the left gastric vessels were ligated. The patient was discharged on April 3.

She was readmitted on December 12 because of hematemesis. She recovered from the hematemesis rapidly but the hospital stay was greatly prolonged because of the onset of vague abdominal discomfort and fever. A diagnosis of probable thrombophlebitis in the portal venous system was made. On June 25, 1945, an attempt was made to perform a portacaval anastomosis but this was found to be technically impossible because of cavernomatous transformation of the portal vein. The patient was discharged on July 11. She was hospitalized in another city during September because of hematemesis. On December 11, 1946 she was readmitted for a second attempt at a portacaval anastomosis, which proved to be technically impossible and was discharged on January 26, 1947. She was again admitted on February 28 because of hematemesis, being discharged on February 28 and on March 4 for another attempt at a portacaval anastomosis. At operation on March 10 the left upper quadrant of the abdomen was explored through a thoracoabdominal incision. An extensive search was made for the stump of the splenic vein which could not be found despite the fact that at the time of the splenectomy it had measured about 2 cm in diameter. Finally an anastomosis

was accomplished between the proximal end of a large branch of the inferior mesenteric vein to the side of the left adrenal vein. The patient made a satisfactory convalescence but it was believed that decompression of the pressure in the portal vein was not satisfactory because of the small diameter of the veins used in the venous shunt. She was discharged 10 days later. She re-entered the hospital because of hematemesis on July 25, being discharged on August 13, and on August 15, being discharged on September 9.

On September 17 she was readmitted for a final attempt to produce a portacaval shunt. At operation on September 20 the abdomen was opened through a long right subcostal incision. Another attempt to isolate the portal vein was fruitless owing to the vascularity of the region and also a porky type of induration in the region of the gastrophrenic ligament. A further search was made for other venous channels to anastomose to the inferior vena cava, but none were found that would have been suitable. The patient made a satisfactory recovery, but remains in the hospital because of further esophagogastrintestinal bleeding.

## DISCUSSION

The construction of blood-vessel anastomoses to shunt the blood flow from one part of the body to another has been perfected in recent years through the stimulus of the work of Whipple,<sup>2</sup> Blakemore<sup>4</sup> and Blalock.<sup>7</sup> The results obtained with portacaval shunts in patients with extrahepatic portal bed block (Bant's syndrome) have been extremely encouraging. In 7 cases in which a satisfactory shunt has been performed, to be reported elsewhere, no patient has bled over periods of two to twenty-two months, although roentgenologic examinations of the esophagus still show the presence of varices. The case reports presented above serve to demonstrate certain points that need emphasis in this new form of treatment. All 4 patients had had previous operations in an attempt to relieve the portal hypertension and bleeding from the esophagogastrintestinal tract, but no operation had been successful. Splenectomy had been performed in 3 cases, and in Case 3, although numerous surgical procedures had been done through both the abdomen and the chest, the spleen had not been removed.

Case 1 had a total of fourteen hospital admissions over a twenty-year period from the onset of the illness. The surgical procedures performed included splenectomy, ligation of the left gastric vein and the periesophageal veins transabdominally, five esophagoscopies, with injection of the esophageal varices with a sclerosing solution. Despite these varied forms of surgical treatment, the patient continued to bleed at intervals. The longest period of respite was from 1932 to 1937. It seems apparent, however, that none of the procedures had much effect on the portal hypertension, since at exploration in October, 1945, the pressure in the portal vein was equivalent to 47 cm. of physiologic saline solution — over four times the normal level. This case is also of interest because of the fact that the previous splenectomy precluded the production of a splenorenal anastomosis and that, owing to a cavernomatous transformation of the portal vein that made it impossible to isolate this vessel, a portacaval anastomosis could not be performed. Instead, the superior mesenteric

<sup>\*</sup>The technique of this operation has been described elsewhere.<sup>8</sup>

vein was isolated at the base of the mesentery and transected, and the proximal end anastomosed to the inferior vena cava just distal to the renal veins. This type of shunt functions because there are no valves in the portal venous system, so that blood can flow in a reverse direction into the inferior vena cava. There are sufficient collateral venous channels around the base of the mesentery to permit blood from the intestines to enter the portal system proximal to the point at which the superior mesenteric vein is interrupted and thus to gain entrance to the venous shunt. The result of this type of

Whether the venous shunt that was constructed — namely, the inferior mesenteric to the left ovarian vein — will produce a satisfactory reduction in the portal hypertension for a long time, it is difficult to say. It is encouraging, however, that the patient had had no further bleeding fourteen months after operation. If further hemorrhage develops it is planned to explore the right side of the abdomen to determine if it is possible to anastomose the portal vein to the inferior vena cava, or possibly the superior mesenteric vein to the inferior vena cava.

In Case 3 eighteen of the thirty-three hospital admissions were for massive bleeding, twelve for melena, and six for hematemesis. During this period the patient had many other bleeding episodes for which he was not hospitalized. This case demonstrates the apparent effectiveness of splenectomy and an end-to-side splenorenal shunt in the control of esophagogastrintestinal bleeding from portal hypertension and the failure of other methods of surgical treatment, which included ligation of the splenic artery and an omentopexy, ligation of the left gastric and coronary veins and an omentopexy, transthoracic ligation of the periesophageal veins and multiple esophagoscopies, with injections of the esophageal varices with a sclerosing solution. The hazard of attempting a portacaval anastomosis, in the presence of the cavernomatous transformation of the portal vein, is also obvious. The common bile duct and the cystic duct were damaged, so that it was necessary to perform a cholecystectomy and a choledochojejunostomy to save the patient's life. Fortunately, he withstood this procedure, and later it was possible to do a splenectomy and an end-to-side splenorenal anastomosis. The successful outcome of the shunt operation is believed to have been due to a number of factors, chiefly, to the utilization of the thoracoabdominal approach, multiple blood-bank transfusions and autotransfusions and the preservation of the left kidney. The importance of preserving the left kidney in this type of surgical procedure cannot be too strongly emphasized, since even with both kidneys this patient developed oliguria for several days and the nonprotein nitrogen level rose to over 100 mg per 100 cc after the splenorenal shunt. It seems very likely that he would have succumbed to uremia if a nephrectomy had been performed. It is still too early to speak of a cure, but at least the patient has had a period of over fourteen months without bleeding, which is the longest respite that he has had since 1937.

In summary, the patient was hospitalized for a total of five hundred and two days because of the portal hypertension. This was 13 per cent of the total time elapsed from the onset of the illness to the last discharge from the hospital. While in the hospital he had five major surgical operations, sixteen esophagoscopies, with injections of sclerosing solution, and a total of sixty-two blood transfusions (Fig 4).

FIGURE 4 Number and Duration of Hospital Admissions for Esophagogastrintestinal Hemorrhages and Therapy in Case 3 and Surgical Procedures Performed

portacaval shunt in this case is encouraging, since there has been no evidence of bleeding over a period of twenty-two months since operation. Another case, with an anastomosis of the superior mesenteric vein to the inferior vena cava, was reported by Bogoraz<sup>8</sup> in 1913, but with a follow-up study of only one month, according to Whipple.<sup>2</sup>

In Case 2 the patient had three hospital admissions. This case also demonstrates the ineffectiveness of a splenectomy and ligation of the periesophageal varices through a transthoracic approach in the treatment of portal hypertension over a prolonged period, although a respite was apparently obtained for a period of about four years. It also demonstrates the impossibility of performing a splenorenal shunt once the spleen has been removed.

Case 4, in which there were eight hospital admissions over a period of three and a half years, also demonstrates the failure of splenectomy and the ligation of the periesophageal varices to control esophagogastrintestinal bleeding, since the patient was readmitted to the hospital because of recurrent hematemesis only eight months after this operation. The case illustrates, in addition, that after a previous splenectomy it may be impossible to perform a satisfactory portacaval shunt of any type. When the spleen was removed the splenic vein was noted to be about 2 cm. in diameter, an excellent vessel with which to do a splenorenal anastomosis. At four subsequent operations it was impossible to find a suitable vessel for a satisfactory shunt. The splenic vein, which had been so large originally, had shrunk down and was replaced by innumerable smaller vessels, none of which were suitable to use. It should be pointed out that at the time the splenectomy was performed in this patient and in 2 of the others the operation of portacaval anastomosis was not a generally accepted surgical procedure. The prognosis is extremely grave, since undoubtedly the patient will continue to bleed and will ultimately succumb from hemorrhage. *In the face of these facts and the good results to date with splenorenal shunts, it seems apparent that a surgeon who does a splenectomy for portal hypertension (Banti's syndrome) should perform a splenorenal anastomosis at the same operation, since this may be the only opportunity for the anastomosis.*

#### SUMMARY

Four cases are presented in 3 of which the results obtained in the treatment of portal hypertension, secondary to an extrahepatic-bed block (Banti's syndrome), by the formation of portacaval shunts were encouraging, since none of the patients with satisfactory shunts has bled since they were performed.

The most satisfactory portacaval shunt seems to be an end-to-side suture type of splenorenal anastomosis performed at the same operation at which the spleen is removed.

In some patients who have had previous splenectomies it may be possible to perform other types of portacaval shunts, such as a superior mesenteric vein to inferior vena cava or inferior mesenteric vein to left ovarian vein. Two patients have gone twenty-two and fourteen months since the shunts were performed without evidence of esophagogastrintestinal hemorrhages.

A direct portacaval anastomosis was not possible in 3 of these cases because of a cavernomatous transformation of the portal veins.

It is believed that a surgeon should not do a splenectomy in a case of portal hypertension unless he is prepared to do a splenorenal anastomosis at the same operation, since this may be the only opportunity to construct a satisfactory shunt.

A longer period of observation is necessary to determine whether the portal hypertension and the tendency to esophagogastrintestinal hemorrhages have been permanently affected.

# SALMONELLA OSTEOMYELITIS OF THE SPINE ASSOCIATED WITH ABDOMINAL AORTIC ANEURYSM\*

## Report of a Case

KLAUS R. DEHLINGER, M.D.†

BOSTON

THE occurrence of an abdominal aortic aneurysm and associated Salmonella osteomyelitis of the spine seems of sufficient interest to warrant a report in some detail, together with autopsy findings.

### CASE REPORT

I P, a 69-year-old married Albanian dishwasher, was admitted to the hospital on November 10, 1945. He had apparently been in excellent health until 6 days before admission, when headaches, nausea and vomiting developed and the stools became loose but not watery. After 2 days

what with pressure and several of which had pale centers. Most of them disappeared within the first 2 hours. The heart and lungs were not remarkable. The abdomen was flaccid, with no tenderness or palpable masses. Peristalsis was active. An easily reducible left indirect inguinal hernia was present. Rectal examination revealed a moderately enlarged prostate.

The temperature was 101.2°F by rectum, the pulse 104, and the respirations 28. The blood pressure was 122/78.

Urinalysis demonstrated a +++ test for sugar and a +++ test for acetone. Examination of the blood disclosed a hemoglobin of 14.5 gm per 100 cc and a white-cell count of 10,400, with 95 per cent neutrophils. The hematocrit was 44 per cent, and the erythrocyte sedimentation rate 22 mm in 1 hour (Westergren method). The nonprotein nitro-

FIGURE 1 Chart, Showing Hospital Course

the bowel movements were apparently normal again. For the next 3 days he experienced several shaking chills with a maximum temperature of 103°F.

The past history revealed an inguinal hernia for which a truss had been worn for 20 years. A brother had diabetes.

Physical examination showed a well developed and well nourished man who was acutely ill, but oriented and in no great distress. He was flushed and perspiring freely. Scattered over the trunk, buttocks and thighs were about ten faintly erythematous, slightly indurated, nontender circinate areas, 1 to 4 cm in diameter, which blanched some-

when with pressure and several of which had pale centers. Most of them disappeared within the first 2 hours. The heart and lungs were not remarkable. The abdomen was flaccid, with no tenderness or palpable masses. Peristalsis was active. An easily reducible left indirect inguinal hernia was present. Rectal examination revealed a moderately enlarged prostate. The temperature was 101.2°F by rectum, the pulse 104, and the respirations 28. The blood pressure was 122/78. Urinalysis demonstrated a +++ test for sugar and a +++ test for acetone. Examination of the blood disclosed a hemoglobin of 14.5 gm per 100 cc and a white-cell count of 10,400, with 95 per cent neutrophils. The hematocrit was 44 per cent, and the erythrocyte sedimentation rate 22 mm in 1 hour (Westergren method). The nonprotein nitro-

gen was 31 mg, and the fasting blood sugar 220 mg per 100 cc. The total serum protein was 6.0 gm per 100 cc, with an albumin of 3.7 and a globulin of 2.3 gm. The blood Hinton test was negative. Cerebrospinal fluid, removed by lumbar puncture, was normal in every respect, including culture. Roentgenograms of the chest and abdomen, as well as retrograde pyelograms, were normal except for a moderate degree of calcification of the abdominal aorta. Both psoas outlines were straight and clear.

The course in the hospital is demonstrated in Figure 1.

(Group B) Thereafter a low grade fever continued but no *Salmonella* organisms could be grown from the stool urine or further blood cultures during the first admission. Sulfadiazine was discontinued after 9 days because of no apparent benefit.

On November 21 the blood showed specific agglutination to *Salmonella* organisms (Group B) in a dilution of 1:2560 the patient's own strain of organisms being used for the test. He complained of constipation which was relieved by frequent enemas. Throughout the first hospital stay no focus of infection could be identified. The patient did not mention any back pain, but complained of discomfort in the lower part of the abdomen which was thought to be due to the hernia, and for this reason he was transferred to the Surgical Service for a herniorrhaphy.

Two days after transfer the patient was discharged because he was considered a poor surgical risk so soon after an acute infection.

The patient was readmitted to the Surgical Service for a herniorrhaphy on December 21 because of frequent cramps

finally discontinued after a total of 34 gm had been given over a period of 14 days because it neither freed the blood stream of *Salmonella* organisms nor brought the temperature to within normal levels.

At first the pain in the lower portion of the spine was present only during a spike in temperature when it was excruciating. Later it became more nearly constant. Tender ness over the same area was elicited about 4 days after the pain had first been noted and at about that time a few transient and faint erythematous spots 5 mm in diameter were observed on the abdomen. Soon thereafter the patient complained of pain in the left knee which became diffusely red and tender to deep pressure. Since a patellar click was absent and roentgenograms of the knee appeared normal no attempt was made to aspirate fluid. On January 4 1946 he fell out of bed but no known injuries resulted. At about that time he had had no bowel movements for 6 days but good results were finally obtained with an enema.

Lateral roentgenograms of the spine on January 18 showed decalcification of the anterior surface of the third lumbar

FIGURE 2 Roentgenograms of the Spine

The film on the left (taken on December 1 1945) shows a normal spine and calcification in the aorta. That on the right (taken on January 24) demonstrates a paravertebral mass displacing the aorta 2.5 cm anteriorly as well as decalcification of the anterior borders of the second and more extensively third lumbar vertebrae.

pains in the region of the hernia since discharge. The stools were loose, but no diarrhea was described.

Physical examination was essentially negative except for the hernia.

The white cell count was 10 800 other laboratory data were within normal limits. The blood Hinton test was again negative.

The temperature rose to 100°F on the 2nd hospital day and herniorrhaphy was postponed for this reason. Thereafter the temperature spiked daily three times to 106°F or over. Sulfadiazine and penicillin were given but medication was again without apparent benefit. Microscopic hematuria was noted on several examinations. *Salmonella* organisms (Group B) were repeatedly obtained on blood culture. There was no evidence of an abscess of the psoas muscle roentgenographically. A barium enema was interpreted as consistent with an inflammatory process in and around the sigmoid because of marked irritability in this region noted during fluoroscopy. The patient complained of pain in the lower portion of the spine for the first time on December 27. Lumbar puncture again gave normal findings.

Because of the persistent chills and high spiking temperature he was returned to the Medical Service on December 31 for streptomycin therapy, which he received intramuscularly every 3 hours in daily divided doses of 2 gm. This was later increased to 4 gm daily. Streptomycin was

vertebra and loss of the usual lumbar lordosis. These findings had not been present on the lateral film of the spine taken 49 days previously. X-ray films on January 24 revealed further decalcification of the third lumbar vertebra anteriorly the margins of the psoas muscles were bowed laterally and there was an area of more or less circumscribed density anteriorly from the second to the fifth vertebra displacing the sclerotic aorta 2.5 cm anteriorly (Fig 2 and 3). Films on January 29 disclosed further decalcification in the third lumbar vertebra with extension of the process to the anterior border of the second lumbar vertebra but the intervertebral space was not diminished. The psoas muscles showed further bulging.

A plaster cast was applied to immobilize the spine. By February 5 the patient had become incontinent of urine and feces and required demerol for relief of pain in the joints of the extremities. He died the next evening. Blood cultures persistently grew out *Salmonella* organisms (Group B) which were also recovered shortly before death from specimens of both stool and urine. The patient's serum agglutinated his own organisms in a dilution of 1:5120 on one occasion. Throughout the hospital stay the diabetes was well controlled with daily doses of 10 to 20 units of protamine zinc insulin.

At autopsy the peritoneal cavity contained no free fluid but along its posterior wall overlying the psoas muscles

there was a marked fluctuant bulge that was maximal over the midline and symmetrically distributed over either side, covering an area of 18 by 20 cm. There was a well defined, left, indirect inguinal hernia that admitted two fingers. The

This aneurysmal sac consisted of adventitia and opened into the aorta over an area 4.5 by 3 cm. No point of rupture could be found, but adjacent to the aneurysm there was evidence of extensive hemorrhage into both psoas

FIGURE 3 The Film on the Left (Taken on December 1) Shows Straight Lateral Margins of Both Psoas Muscles, Whereas That on the Right (Taken on January 24) Shows Marked Bulging in Both Muscles

small intestine showed no evidence of ulceration, acute inflammation or strangulation. The spleen weighed 280 gm and on cut section was deep purplish red, soft and mushy with ill defined malpighian corpuscles and markedly congested pulp. There were no verrucae or vegetations on

FIGURE 4 Autopsy Specimen, Showing Destruction of the Anterior Border of the Vertebral Body, with No Narrowing and Only Slight Involvement of the Intravertebral Space Anteriorly

any of the heart valves. The thoracic aorta showed a mild degree of atherosclerosis, and the abdominal aorta revealed marked calcification. Overlying the third lumbar vertebra, an aneurysm protruded from the posterior wall of the aorta and extended 3.5 cm inferiorly and laterally on either side

muscles. Interconnecting abscesses, filled with thick, brown, moderately foul-smelling pus lay directly posterior to the aneurysmal sac, with extensive involvement. In this area the vena cava had been invaded by a walled-off abscess, 2 by 2 cm in diameter, which projected into its lumen as a flat polypoid mass. The anterior portion of the bodies of the second and more extensively the third lumbar vertebra were necrotic and crumbly and bathed in pus (Fig 4). The psoas muscles were fusiform, dark purplish red and nearly twice their normal size, after fixation each measured approximately 23 cm in length and 9 cm in width. Multiple cross-sections showed them to be distended by an extensive blood clot, contiguous to the lateral projections of the aneurysm and measuring about 7 by 4 cm. Further sectioning of the muscles near their points of origin disclosed multiple abscesses, some interconnecting and all relatively thick walled and containing purulent material similar to that observed elsewhere. Culture grew out *Salmonella* organisms (Group B).

The brain was normal except for marked generalized arteriosclerosis. No other organs were remarkable.

## DISCUSSION

The combination of aneurysm of the abdominal aorta and *Salmonella* osteomyelitis of the spine makes this a most unusual case. The latter condition has occasionally been reported in foreign journals, but no reports could be found in the American medical literature.

Infection of the spine comprises 0.2 per cent of all cases of osteomyelitis.<sup>1</sup> Although it is usually due to tuberculosis, typhoid being the next most frequent cause, at least in the older literature, it has been reported secondary to many infections, Schmorl and Junghanns<sup>1</sup> giving references to papers reporting twenty-five different etiologic organisms.

There are conflicting reports regarding the frequency of osteomyelitis as a complication of Salmonella infection. In 1382 cases of paratyphoid infection, Webb-Johnson<sup>2</sup> was able to recover the organism from bones or joints only twice, although many of the patients had painful joints in which the aspirated fluid was sterile. Seligmann<sup>3</sup> reported only 3 cases with osteomyelitis out of 1000 bacteriologically proved Salmonella infections. These were due to organisms from Group B (*Salmonella typhimurium*) and Group D (*S. enteritidis* and *S. panama*), although those in Group C (specifically *S. choleraesuis*) are supposedly more invasive for human beings. Harvey,<sup>4</sup> reviewing the literature on the last organism, found 15 of 71 patients (over 20 per cent) to have manifestations of involvement of the bones or joints. He did not, however, specifically state that organisms were recovered from these bones or joints. He also mentioned a current hospital case of osteomyelitis of the spine but did not report it in detail. This is the only reference of this condition found in the American medical literature. In the case reported above the Salmonella infection may have involved the knee as well as the spine, although no culture was taken of the former.

For a better understanding of the two fundamentally different types of pathologic processes in the vertebral bodies (infection and pressure erosion) an attempt is made to reconstruct the sequence of events as they occurred in this patient. It is postulated that the aneurysm of the abdominal aorta leaked out blood, providing a culture medium and finally resulting in a prevertebral abscess. The erosion of the vertebral bodies was probably started directly by the aneurysm and continued by the transmitted aortic pulsation through the prevertebral abscess, which developed between the aneurysm and the vertebrae. Only later did the infection spread through the wall of the abscess and actually invade the bone. Although the evidence is incomplete, the data are all in support of this thesis.

As for the aneurysm, its origin could have been syphilitic, mycotic or arteriosclerotic.

Although aortic aneurysms are usually syphilitic, those below the renal arteries, as in the case reported, are rarely due to *Treponema pallidum*. Furthermore, this patient had several negative serologic tests for syphilis during life, and no autopsy findings were suggestive of the disease.

The possibility of a mycotic aneurysm must be seriously considered. Such aneurysms usually result from infections from within, 90 per cent being due to subacute bacterial endocarditis or subacute bacterial endarteritis, secondary to a congenital vascular anomaly such as patent ductus arteriosus or coarctation of the aorta. Stengel and Wolferth<sup>5</sup> collected 217 cases of mycotic aneurysm of which 187 were due to subacute bacterial endocarditis. Of the remaining 30, the authors state that 6 were "associated" with osteomyelitis, but no mention is

made of which bones or vessels were involved or whether the aneurysm was adjacent to the osteomyelitis in any of the cases. Thus it is not known if the aneurysms were produced by direct extension or by infected emboli in these cases. Apparently the only reported cases of mycotic aortic aneurysms due to direct extension from osteomyelitis of the spine were in patients with Pott's disease. Interestingly enough, Klotz<sup>6</sup> does not refer to direct extension mycotic aneurysms due to osteomyelitis in his monograph on aneurysms, and Osler<sup>7</sup> does not even mention direct extension mycotic aneurysms of any kind in his long chapter on aneurysms, even though he is said to have been the first to adopt the term "mycotic."

It is unlikely that the case described above had a mycotic aneurysm from within, since there was no subacute bacterial endocarditis; however, it is not completely impossible that an infected embolus was lodged there after Salmonella bacteremia. It is also very unlikely that this was a mycotic aneurysm from without, by direct extension of the infected vertebral body, because at autopsy the wall of the aneurysm was found to consist of adventitia.

Arteriosclerotic aneurysm therefore seems the most tenable etiology in this case. Kampmeier,<sup>8</sup> in reviewing the literature on abdominal aortic aneurysms in 1936 collected 313 cases and added 68 more. Of these he considered "very few" to be arteriosclerotic, the great majority being syphilitic. However, more recently in other series incidences of 21 per cent (20 of 96 cases)<sup>9</sup> and 17 per cent (8 of 48 cases)<sup>10</sup> have been reported, indicating that such an etiology is not uncommon. The evidence of marked calcification of the abdominal aorta, as well as of other arteries visible in the x-ray films and at autopsy, the microscopical picture of the aorta and the patient's diabetes all support the arteriosclerotic etiology.

Erosion involving the anterior portion of the vertebral bodies and sparing the intervertebral structure is typical of external pressure as seen most commonly from aortic aneurysms, and not of an infectious process. When looked for, vertebral erosion secondary to abdominal aortic aneurysm is often seen.<sup>8-10</sup> Farmer<sup>11</sup> reported such a case with striking ante-mortem roentgenograms of the spine and pictures of the spine removed at autopsy. In the Army Medical Museum at Washington, D. C., there is a specimen of four adjacent vertebral bodies with erosion due to aortic aneurysm. The erosion may become so marked as to result in compression of the spinal cord by the aneurysm.<sup>11, 12</sup>

In contrast, infections of the spine do not usually begin in the central or anterior portion of the vertebral body but in the intervertebral space and adjacent bony surfaces.<sup>13-16</sup> The earliest x-ray changes are narrowing of the intervertebral space caused by destruction of the intervertebral tissues, as well

as questionable involvement of the adjacent bone. This narrowing is usually asymmetrical, resulting in a kyphoscoliosis and a loss of the usual lumbar lordosis, which is also due in part to muscle spasm. The reports of *Salmonella* spondylitis in the foreign medical literature indicate that it usually occurs in the lumbar spine and follows the typical course of any infectious spondylitis. Healing by ankylosis is the rule. Ssokoloff<sup>16</sup> was able to collect 5 such cases due to *Salmonella*, and reports of 6 others were found.<sup>1, 12, 14, 16, 17, 18</sup> It is interesting in passing to note the rarity of psoas abscess associated with nontuberculous osteomyelitis of the spine, which this patient had. In fact, Hesse<sup>14</sup> could not find a report of any such case, although the abscesses do occur in staphylococcal osteomyelitis of the spine.

### SUMMARY

A case of abdominal aortic aneurysm and adjacent *Salmonella* osteomyelitis of the spine with autopsy findings is reported.

An attempt is made to analyze the sequence of events occurring in this case.

It is concluded that the abdominal aortic aneurysm was primary and arteriosclerotic in origin, whereas the *Salmonella* osteomyelitis of the spine developed secondarily.

A review of the literature reveals that *Salmonella* osteomyelitis of the spine is very uncommon, and this is apparently the first case in which either aneurysm or psoas abscess was found associated with this condition.

Streptomycin, given over fourteen days in a total dose of 34 gm, apparently had no effect whatsoever on the *Salmonella* infection.

# BONE AND JOINT PAIN IN LEUKEMIA, SIMULATING ACUTE RHEUMATIC FEVER AND SUBACUTE BACTERIAL ENDOCARDITIS\*

MARK AISNER, M.D.† AND THOMAS B. HOXIE, M.D.‡

BOSTON

**A**LTHOUGH pain along the bones and in the joints in the acute leukemias has been reported in the literature from time to time, its diagnostic significance has not been sufficiently stressed and its confusion with acute rheumatic fever has been the rule rather than the exception. This confusion has depended to a large extent upon the many similarities in the symptomatology of the leukemias and rheumatic fever. In either of these conditions there may be asthenia, palpitation, dyspnea on exertion, epistaxis, fever, bone and joint pain, abdominal pain, pallor, purpuric manifestations, lymphadenopathy, splenomegaly, anemia, tachycardia, accentuation of the heart sounds and cardiac murmurs. Additional diagnostic difficulties arise in the early stages of leukemia when lymphadenopathy, splenomegaly, hepatomegaly and a clear-cut blood picture may be absent. The importance of a correct diagnosis can be appreciated especially from the standpoint of management and prognosis.

Although it is not our purpose to review the entire literature pertaining to this subject, mention of a few of the outstanding contributions is made. That pain and tenderness along the bones and in the joints constitute a prominent feature of the symptomatology of the leukemias was pointed out as early as 1889 by Ebstein<sup>1</sup> and 1895 by Fraenkel.<sup>2</sup> In 1913 Strauch<sup>3</sup> again mentioned that in some cases of acute lymphatic leukemia the onset is marked by pain, and swelling of the joints, resembling articular rheumatism. Seward<sup>4</sup> reported a case in a thirty-one-year-old man who died of lymphatic leukemia and who presented during life severe pain and swelling of the hips and shoulders. Poynton and Lightwood<sup>5</sup> described a case in a three-and-a-half-year-old girl with acute lymphatic leukemia and multiple, migratory joint pain recorded as "fitting from joint to joint," and involving the ankles, knees, wrists and fingers. In a series of 28 cases of leukemia in children reported by Wollstein<sup>6</sup> pain over the bones occurred in 10. In a larger series studied by Cooke<sup>7</sup> 13 out of a total of 50 patients had "rheumatoid pain," which was the most prominent symptom in 6 cases. Baldridge and Awe<sup>8</sup> found acute arthritis in 13 of 20 patients under twenty-one years of age with lymphogenous leukemia. Similar reports have appeared by Smith,<sup>9</sup> Sutton and Bosworth,<sup>10</sup> Conybeare<sup>11</sup> and others.

It is interesting to note that in the majority of the reported cases the diagnosis of rheumatic fever was originally made.

The coexistence of leukemia and rheumatic fever has been regarded as extremely rare. Ehrlich and Forer<sup>12</sup> reported a fatal case in an eleven-year-old girl with acute myelogenous leukemia, who presented pain, tenderness, redness and swelling about the joints, so that the condition seemed indistinguishable clinically from acute rheumatic fever. At autopsy the heart showed both leukemic infiltration and Aschoff bodies. No similar case, according to the authors, was found in the literature.

Occasionally, the articular manifestations of the leukemias simulate rheumatoid arthritis. This is particularly so in patients presenting fusiform swelling of the proximal interphalangeal joints of the fingers. Such cases have been reported by Karelitz<sup>13</sup> and Flinn.<sup>14</sup> Differentiation from Still's disease, which may be accompanied by generalized enlargement of the lymph nodes and by splenomegaly, is important in children.

Foraker<sup>15</sup> has classified bone and joint involvement in the leukemias under the following headings: tumor-like lesions of bones in chloroma, tumors of leukoblastic origin in bones and destructive and absorptive lesions leading to softening, defects and fractures, periosteal elevations, particularly about the joints, arthritis, often of the acute recurrent type, more rarely of the chronic infectious type, osteosclerosis of the bone marrow, and osteomyelitis. Some overlapping of these categories frequently occurs. Patients with acute arthritis, for example, often show periosteal elevations on x-ray study.

Pathologically, apart from tumor formation, leukemic infiltration has often been demonstrated in cases showing periosteal elevations. However, not all patients who exhibit joint pain during life present articular changes on pathological examination. In the report by Seward<sup>4</sup> of severe joint pain during the course of lymphatic leukemia no gross or microscopical abnormalities of the joints were found on post-mortem study. Baldridge and Awe<sup>8</sup> were able to demonstrate lymphoblastic infiltration of bone in 1 of 55 cases of lymphogenous leukemia and in 1 of 14 cases of subleukemic lymphogenous leukemia.

This report presents 4 cases of acute lymphatic leukemia in which bone and joint pain were outstanding features. In 2 cases a diagnosis of acute rheumatic fever was made at the time of admission to the hospital. In a third case the findings so

\*From the First and Third (Tufts) Medical Services, Boston City Hospital and the Department of Medicine, Tufts College Medical School.

†Assistant professor of medicine, Tufts College Medical School; physician to out-patients, Boston City Hospital.

‡Formerly, resident physician, Third Medical Service (Tufts) Boston City Hospital.

closely resembled those of subacute bacterial endocarditis that this diagnosis was made on entry. The fourth case was correctly diagnosed on admission, but it is interesting to note that the referring physician considered the symptoms rheumatic in origin. These cases fall into the fourth (arthritic) category of Forkner,<sup>15</sup> cited above.

### CASE REPORTS

**CASE 1\*** J G (R B B H 1849), a 7-year-old girl, was admitted to the hospital on July 18, 1939, with a complaint of pain and tenderness in the right knee of 4 weeks' duration. She had had several episodes of migratory joint pain, involving the knee, elbows and ankles and the cervical and lumbar areas of the spine. On one occasion the right elbow joint had remained swollen for 3 days. She also complained during this period of recurring, transient, right-lower-quadrant pain associated with nausea and on several occasions with vomiting. There had been a slight nonproductive cough. The temperature had varied between 99 and 100°F, and the pulse between 100 and 140.

An aunt was said to have a "leaking valve," and another was known to have definite rheumatic heart disease.

On physical examination the patient did not appear to be acutely ill. There was a slight malar flush. No lymphadenopathy was present. Examination of the heart showed no enlargement, a forceful apical beat and a reduplicated pulmonic second sound. There were no murmurs or thrills. The tip of the spleen was palpable at the end of deep inspiration. The right knee was painful on motion, permitting flexion to 90°.

The temperature was 99.5°F, and the pulse 135. The blood pressure was 105/75.

Examination of the blood disclosed a red-cell count of 4,560,000, with a hemoglobin of 80 per cent, and a white-cell count of 5550, with 49 per cent neutrophils, 50 per cent lymphocytes and 1 per cent basophils. The platelets appeared normal in number.

During the hospital stay the patient experienced several episodes of fleeting joint pain involving the elbows, knees and ankles. She also complained frequently of lower abdominal pain, associated at times with nausea and vomiting. At the end of 10 weeks the liver and spleen were readily palpable, and the blood revealed the development of a moderate secondary anemia. There was a progressive rise in the percentage of lymphocytes and a fall in the number of platelets. Because of the progressive anemia, blood transfusions were resorted to. This procedure aided in maintaining the hemoglobin level between 80 and 85 per cent and the red-cell count between 4,000,000 and 4,500,000. The white-cell count varied between 4000 and 5000. On smear 90 per cent of the cells were lymphocytes. Fourteen weeks after admission purpuric spots appeared over the body, and a few large ecchymoses were noted. The cervical, axillary and inguinal nodes became enlarged. The hemoglobin level had fallen to 57 per cent, the red-cell count to 3,610,000, and the platelet count to 58,000. At the end of 16 weeks there was a further drop in the hemoglobin to 35 per cent, in the red-cell count to 2,080,000 and in the platelets to 15,000. The white-cell count was 3950, and on smear only lymphocytes were seen, of which 60 per cent were classified as large and the remainder as blast and atypical forms. Considerable bleeding from the gums took place, and on one occasion hematemeses occurred. Terminally there were repeated convulsions, and the respiratory rate reached 68 per minute, and the pulse rate 160 per minute. The patient died approximately 18 weeks after admission.

Permission for autopsy was not obtained.

**CASE 2** J MacR (B C H 862,131), a 19-year-old boy, was admitted to the hospital on June 1, 1937. He had been well until 8 weeks before entry, when he had experienced episodes of vomiting continuing over a period of 4 weeks. Four weeks prior to admission he had complained of steady pain in the right shoulder and in the joints of the right foot, the latter associated with local swelling and tenderness and

severe enough to make weight bearing impossible. On the day of entry he had had two moderately severe nosebleeds.

Except for vague muscular pains during the last year, the past history was noncontributory.

On physical examination the skin and mucous membranes were moderately pale, but otherwise not remarkable. Venous and arterial pulsations in the neck were very prominent. The throat was injected. The heart sounds were of booming quality, with accentuation of the pulmonic second sound. A loud, harsh, systolic murmur was heard along the left border of the sternum, best at the second left interspace. The liver and spleen were not palpable. There was slight local swelling, redness and heat over the bones of the right foot, with definite tenderness on pressure. Examination of the right shoulder was negative.

The temperature was 99.6°F, and the pulse 90. The blood pressure was 120/64.

Examination of the blood revealed a red-cell count of 2,050,000, with a hemoglobin of 38 per cent, and a white-cell count of 13,400, with 48 per cent neutrophils, 50 per cent lymphocytes and 2 per cent monocytes.

Because of the marked anemia the patient received several blood transfusions, with little response in either the hemoglobin level or the red-cell count. He continued to have repeated, moderately severe nosebleeds while on the ward. He complained considerably of pain in the joints of the right foot and later of generalized joint pain, especially marked in the left elbow, which had become moderately swollen and very tender to touch. The value for blood uric acid was 18.5 mg per 100 cc. On the 23rd hospital day the white-cell count was 7600, and the smear showed 50 per cent lymphocytes. The liver and spleen were now palpable, and their size increased rapidly up to the time of death. On the 29th day the white-cell count had risen to 144,000, with 29 per cent lymphocytes, mostly immature forms. There was generalized enlargement of the lymph nodes. Acute ulcerations of the mucous membranes of the mouth developed, and the patient died suddenly on the 37th hospital day.

Autopsy† revealed leukemic infiltration of the spleen, liver, kidney, anterior mediastinal connective tissue, lymph nodes, and lumbar, sternal, femoral and tibial bone marrow. Small collections of lymphocytes were found in the synovia of the left elbow joint. The renal tubules were packed with deposits of uric acid.

**CASE 3** R C (B C H 919,897), a 15-year-old schoolboy, was admitted to the hospital on November 11, 1938. One month before entry migratory joint pain involving the right knee, left ankle, wrists and elbows had developed. The joints were warm, painful on motion and tender to touch, but not remarkably swollen. These symptoms persisted for 1 week, after which he noticed progressive pallor of the skin. He became feverish, and for the first time experienced night sweats. Two weeks after the onset of the illness he complained of soreness of the finger tips, aggravated by pressure. On the day prior to entry he had an episode of sudden blurring of vision in the left eye, which rapidly cleared up. Except for palpitation, he offered no additional complaints.

Physical examination disclosed a patient who appeared acutely ill. The skin had a definite café au lait color. The throat was moderately injected. The apical beat was diffuse and forceful, and the left border of cardiac dullness was percussed just outside the midclavicular line. The heart sounds were rapid and booming, and the pulmonic second was greater than the aortic second sound. A loud, blowing systolic murmur was heard at the apex. The spleen was felt two fingerbreadths below the left costal margin. The liver was not palpable. A few, small cervical, axillary and inguinal nodes were found. There were no petechiae. The joints were normal.

The temperature was 101°F, and the pulse 120. The blood pressure was 108/72.

Examination of the blood showed a red-cell count of 1,520,000, with a hemoglobin of 30 per cent, and a white-cell count of 3800, with 10 per cent neutrophils, 16 per cent small lymphocytes, 6 per cent large lymphocytes, 67 per cent lymphoblasts and 1 per cent monocytes. The platelet count was 45,000. Repeated blood cultures were negative. An electrocardiogram was interpreted as indicative of myocardial damage. X-ray examination of the chest was negative.

\*We are indebted to Dr. Marshall G. Hall of the Robert Breck Brigham Hospital, for permission to report this case.

†Boston City Hospital No. 37-64.

The course was progressively downhill. On the 2nd hospital day considerable hemorrhage occurred from the gums and on the 3rd day there was a retinal hemorrhage in the left eye. Repeated blood transfusions had no effect on the hemoglobin level or the red-cell count. The white-cell count rose to 20,000 on the 3rd day, and fell to 4,200 by the 6th day. The temperature remained elevated throughout the illness and was septic in type. The patient died on the 18th hospital day. The white-cell count prior to death was 3,800 with no essential changes in the blood smear.

Permission for autopsy was not obtained.

**CASE 4.** M. W. (B. C. H. 870 403), a 14-year-old Negroess was admitted to the hospital on August 19, 1937, too ill to give a satisfactory history. From the mother it was learned that the patient had complained for the past year of weakness and fatigability. For 7 weeks prior to admission there had been considerable joint and muscle pain, and for 4 weeks slight intermittent bleeding from the nose and gums. Three months previously she had had a severe sore throat which had improved after 1 week. Amenorrhea had been noted for the last three months.

Physical examination disclosed a patient who appeared acutely ill complaining mostly of abdominal pain. The mucous membranes were very pale. There was evidence of recent bleeding from the gums. The tonsils were red, large and ulcerated. A few small nontender lymph nodes were felt in the neck. Moist rales were heard at both bases. The heart sounds were of booming quality and a loud systolic murmur was heard at the apex. The liver edge was palpated six fingerbreadths, and the spleen three fingerbreadths below the costal margin. A round tender mass was felt supra-pubically consistent with a pregnancy of 4 months duration. The blood pressure was 110/58.

Examination of the blood showed a red-cell count of 1,330,000 with a hemoglobin of 28 per cent and a white-cell count of 278,000. The white cells on smear were predominantly immature lymphocytes. There was a marked reduction in the number of platelets.

During the brief hospital stay the patient complained of constant, generalized abdominal pain. She died suddenly approximately 15 hours after admission.

Autopsy\* revealed leukemic infiltration of the spleen, liver, pancreas, stomach, ileum, kidney, adrenal glands, ovaries and uterus and vertebral costal sternal femoral and tibial bone marrow, as well as lymph nodes throughout the body. The joints were not examined. The uterus contained a fetus estimated to be 18 weeks old, whose tissues were free of leukemic invasion on microscopical examination.

## DISCUSSION

The cases presented above illustrate very clearly the similarities in the symptomatology and physical signs, at certain stages, of leukemia, acute rheumatic fever and subacute bacterial endocarditis. Although numerous reports in the literature demonstrate the similarities between leukemia and acute rheumatic fever, little reference to the difficulty in differentiating leukemia from subacute bacterial endocarditis is to be found. However, the fact that confusion between these two diseases has occurred is brought out in the following statement by Herrick<sup>14</sup>:

I do not remember to have seen malignant endocarditis mistaken for acute leukemia, but I have seen the latter looked upon as malignant endocarditis. The fever rapidly developing anemia, the hemorrhagic lesions in the skin, the enlarged spleen and a loud endocardial murmur may make the resemblance quite strong.

The various symptoms and signs common to these illnesses may be listed as weakness, fatigability, weight loss, fever, sweats, bone and joint pain,

muscle pain, painful fingertips, abdominal pain, anorexia, vomiting, epistaxis, pallor, shortness of breath, palpitation, anemia, hemorrhagic skin lesions, tender, warm, swollen joints, lymphadenopathy, splenomegaly, tachycardia, accentuation of heart sounds and cardiac murmurs. Certain clinical findings merit further comment regarding differential diagnosis.

## Blood Picture

It should be remembered that anemia and thrombocytopenia are not essential features of the early stages of leukemia. Hence, the finding of normal values for hemoglobin and normal counts for red cells and platelets does not exclude leukemia as a diagnosis. This is clearly demonstrated in Case 1, in which the hemoglobin was 80 per cent, the red-cell count 4,560,000 and the platelets normal a month after the onset of symptoms. Later in the course of the disease anemia and thrombocytopenia become prominent, attaining a severe grade in most cases. The degree of anemia, when present, is only of limited value in differential diagnosis. According to Wilson<sup>17</sup> secondary anemia is usually present during rheumatic activity, and its degree parallels the severity and duration of the disease. In a series of cases from the New York Hospital the average red-cell count was 3,700,000, and the range from 2,800,000 to 4,500,000. The anemia is usually not severe enough to warrant blood transfusions, unless repeated and severe nosebleeds have occurred. In the presence of profound degrees of anemia and findings simulating acute rheumatic fever leukemia must be considered in the differential diagnosis. Cases 3 and 4 illustrate this point, the red-cell count in the former having been 1,500,000 and that in the latter 1,300,000 at the time of admission to the hospital. The difficulty in differential diagnosis based on this point, however, is well shown by Case 2, in which repeated and severe epistaxes occurred and in which the red-cell count on admission was 2,050,000. That diagnosis cannot always be made on a single finding is again brought out by Poynton's<sup>18</sup> mention of a rare case of rheumatic fever in which the anemia proved fatal. Severe anemia in rheumatic fever has also been reported by Hubbard and McKee.<sup>19</sup>

The response of the anemia to blood transfusion is not in itself diagnostic. Although, generally speaking, the anemia in leukemia does not respond readily to this procedure, especially in the presence of hemorrhage, a fair response may be obtained in the early stages of the illness, as in Case 1, in which the hemoglobin level was brought up from 63 per cent to 85 per cent within a period of three weeks. Later in the course of the disease transfusions were of no avail.

The presence or absence of leukocytosis may be of some aid in diagnosis. Leukocytosis is the rule in cases of active rheumatic fever associated with

\*Boston City Hospital No. 37 542.

joint pain<sup>20</sup> The average white-cell count, according to Wilson,<sup>17</sup> is 13,200, the range being from 8000 to 23,000 In 91 per cent of her cases the white-cell count was over 9000 Consequently, the presence of leukopenia associated with symptoms referable to the bones and joints should make one suspect conditions other than acute rheumatic fever The differential count is of great importance Ordinarily, there is a rise in the percentage of neutrophils during active rheumatic fever<sup>20</sup> The finding of lymphocytosis, especially when associated with leukopenia, is presumptive evidence against rheumatic fever, even though the clinical manifestations point to that diagnosis Cases 1 and 2, both of which presented leukopenia and moderate lymphocytosis, were erroneously considered to be acute rheumatic fever at first No difficulties arise in differential diagnosis when the blood picture is what is usually considered more typical of leukemia

### *Joint Pain*

Any group of joints may be involved in either leukemia or acute rheumatic fever The clinical features of one may be indistinguishable from those of the other There may be transient arthralgias, migratory joint pain, persistent pain in one or more joints and all the local manifestations of heat, redness and swelling The response of the joint pain to salicylates does not help in distinguishing one disease from the other Although cases have been reported in which salicylates have failed to relieve the joint pain in leukemia,<sup>21</sup> the patient in Case 1 obtained definite benefit from them

The determination of the level of blood uric acid may be of decided value in the differential diagnosis of the two diseases In conditions like leukemia, in which there may be considerable destruction of blood and liberation of nucleoproteins, the value for blood uric acid may become elevated, in some cases markedly so The blood level in Case 2 was 18.5 mg per 100 cc, and at post-mortem examination the renal tubules were packed with deposits of uric acid Hench<sup>22</sup> brought out the point that the acute arthritis in leukemia should be suspected as gouty Unfortunately, values for uric acid were not obtained in the other cases reported above Hyperuricemia is not present in acute rheumatic fever

### *X-ray Films of Bones and Joints*

Numerous reports have appeared in the literature concerning bone and joint changes as visualized by x-ray examination in cases of leukemia An excellent review of the literature on this subject is presented by Connor<sup>23</sup> Among the changes noted were subperiosteal elevation, osteosclerosis, osteoporosis, cortical stratification, rarefaction at the ends of the long bones, spontaneous fractures, large tumor masses in the upper ends of the long bones, various osteolytic lesions and medullary striations These lesions are produced essentially by the encroachment

of leukemic cells on the normal bony structures All cases of leukemia, however, do not show bone changes on x-ray study In a review by Wollstein<sup>6</sup> of 10 cases of leukemia in children presenting bone and joint pain as a symptom, x-ray evidence of bone changes was found in 6, consisting of cortical destruction, rarefaction and periosteal elevation X-ray studies of all the bones in Case 1, taken eight weeks after the onset of the illness, were entirely negative The commonest x-ray finding is periosteal elevation It should be realized that this abnormality is far from specific for the leukemias It may be seen in a number of different conditions, among them osteomyelitis, scurvy, congenital syphilis and bone tumors The cause of pain in the joints and along the bones in cases of leukemia is generally attributed to the invasion of the bony and articular structures by leukemic cells, although such invasion has not been consistently demonstrated No satisfactory explanation why this symptom is more frequent in younger patients has been given

In conclusion it is emphasized that the presence of bone and joint pain, apart from that of traumatic origin, in young people does not invariably mean acute rheumatic fever The differential diagnosis of this symptom should include a consideration of many conditions, among them undulant fever, poliomyelitis, osteomyelitis, scurvy, rickets, syphilis, gonorrhea, tuberculosis, Haverhill fever, Hodgkin's disease and Still's disease A discussion of the differential diagnosis of these conditions is beyond the scope of this paper We have simply attempted to demonstrate the similarity in the symptoms and signs of leukemia and acute rheumatic fever, and to point out certain features that may be of value in their differential diagnosis, especially in the earlier stages of leukemia when the usual typical features may be lacking

### SUMMARY

Four cases of acute lymphatic leukemia, 3 presenting signs and symptoms simulating those of acute rheumatic fever and 1 simulating those of subacute bacterial endocarditis, are presented

Certain pitfalls and aids in the differential diagnosis between acute rheumatic fever and acute lymphatic leukemia are discussed

Complete examination of the blood should be performed routinely in all cases presenting bone or joint pain as a symptom

The findings that point to the diagnosis of lymphatic leukemia rather than of acute rheumatic fever are leukopenia persistent in the presence of an active clinical course, leukopenia or leukocytosis associated with an increase in the percentage of lymphocytes and bone changes on x-ray examination

The various bone changes in leukemia visible by x-ray study are enumerated

The importance in differential diagnosis of other disorders that cause bone and joint pain in young people is mentioned

## MEDICAL PROGRESS

### ORTHOPEDIC SURGERY

#### II Growth and Inequality of Leg Length in Poliomyelitis\*

JOSEPH S BARR, MD†

BOSTON

ALTHOUGH it is not the purpose of this paper to consider in detail the general factors that as a rule affect equally the growth of both limbs, a few words about normal growth may not be amiss.

Nature produces regularly in the human being, as in many other animals, paired, symmetrical, mirror-imaged extremities of essentially identical length. These normal growth processes are complex and dynamic, beginning with the union of an ovum and a sperm, which carry in their chromosomes the hereditary factors (genes) that determine whether the person will have the muscular legs of an athlete, the shapely limbs of the chorus girl or the misshapen contours of the achondroplastic dwarf.

Added to the hereditary are many environmental factors that affect normal development. The diet of the pregnant mother<sup>1, 2</sup> and of the child during its whole growing period is of great importance.<sup>3</sup> Vitamins, proteins, minerals and carbohydrates are needed in adequate amounts. The pituitary, thyroid, adrenal and other glands of internal secretion furnish hormones that directly or indirectly play an important role in determining the physical characteristics of the person and of his lower extremities.

The over-all length of the lower limbs consists in the length of the femur and tibia, with some minor increments represented by the articular cartilage of the hip, knee, ankle and subastragalar joints and by the bones of the hind foot (os calcis and talus).

Longitudinal growth of the long bones is the result of the highly specialized activity of the epiphyseal plates. Cartilage cells arranged in columnar fashion multiply, pushing the epiphysis at either end of the bone away from the diaphysis. At the same time the older cells of the epiphyseal plate nearest the diaphysis mature and are replaced by bone. Thus, during the growing period, the cartilage plate maintains an approximately constant thickness while the shaft of the bone increases in length. At some time in adolescence the growth potential of the epiphyseal plate becomes exhausted, the cartilage cells reach senescence and die, and the diaphysis unites with the epiphysis, leaving at most a faint transverse x-ray shadow to indicate the site of the epiphyseal plate. According to Green<sup>4</sup> the average skeletal age for cessation of longitudinal growth of the femur and tibia is fourteen years and three months in girls and sixteen years and three months in boys. There are wide variations from this average, which become less pronounced if true skeletal age is substituted for chronologic age. For the determination of skeletal age, the work of Todd<sup>5</sup> on skeletal maturation has given a reasonably satisfactory set of standards.

\*Presented at the Convention of the Georgia W. m. Springs Foundation September 17, 1947.

There is cessation of growth long before fusion of the epiphysis and diaphysis occurs. Although x-ray films may show the epiphyseal line to be open, all growth from that cartilage plate may have ceased.

The epiphyseal plates of the femur and tibia do not contribute equally to the longitudinal growth of

TABLE 1 *Contribution of Femoral and Tibial Epiphyses to Longitudinal Growth of the Lower Extremity*

the lower extremity. Although exact values derived from observation of a large series of cases are not available, the figures presented in Table 1 appear to be reasonably accurate.

### UNEQUAL GROWTH

Many conditions may result in asymmetrical growth and unequal length of the legs. These conditions may be classified in three main groups

FIGURE 1 *Incidence of Discrepancy in Leg Lengths among 371 Cases of Poliomyelitis in Which the Onset Occurred before the Age of Sixteen Years*

growth retardation due to local interference at an epiphyseal plate, growth retardation due to interference from remote causes, and factors that may stimulate unilateral growth.

### Local Interference at an Epiphyseal Plate

Congenital abnormalities of the epiphyseal plate, tumors, infections and trauma are some of the more important types of pathologic processes that can directly impair the ability of an epiphyseal plate to keep pace with its counterpart.

A few children are born with congenital abnormalities in which one or more epiphyseal plates are absent or deficient. Osteomyelitis or tumor may invade an epiphyseal plate, destroying the cartilage cells and thus causing unequal growth. A fracture through an epiphysis may cause premature union of the epiphysis, with resultant shortening of the extremity.

### Interference from Remote Causes

Any process that results in unequal motor power in the two extremities may cause unequal growth. Poliomyelitis is the most important member of this class, which also includes spastic, obstetric and traumatic nerve palsies. The flaccid paralysis of poliomyelitis, obstetric and traumatic nerve lesions is associated with much more shortening than is found in spastic paralysis.

Disuse is a potent cause of growth retardation. Prolonged immobilization of an otherwise normal extremity may cause retardation of growth and premature ossification of normal epiphyseal plates. Numerous observers have noted that tuberculosis of the hip treated by prolonged immobilization of the whole extremity in a plaster cast results in extreme atrophy and shortening of up to 4 or 5 inches. Recently, attention has been called to the fact that this may be due to premature closure of the epiphyses about the knee.<sup>7, 8</sup>

Another example of the effect of unilateral immobilization on growth may be cited. Cases of unilateral Legg-Perthes disease, treated by prolonged bed rest but with little or no immobilization of either extremity, recover with minimal shortening—usually not exceeding 1 cm. This minimal shortening is probably due to local interference with growth at the proximal femoral epiphysis. But a similar series of cases, in which the affected leg was protected by a nonweight-bearing brace for an equally prolonged period, showed more shortening (1 to 3 cm) than those treated by bed rest. It is well known that growth and form are directly influenced by function. It is therefore equally true that disuse or restricted use of one extremity will adversely affect its development.

### Unilateral Growth

Unilateral stimulation of growth occurs rarely. The conditions in which it most often occurs are osteomyelitis, vascular tumor such as hemangioma, arteriovenous fistula and fracture of the diaphysis of growing bones. The common denominator appears to be increased blood supply to the affected ex-

trinity, giving a favorable environment for rapid growth of the epiphyseal plates

#### EFFECT OF POLIOMYELITIS ON GROWTH OF LOWER EXTREMITIES

In the preparation of this paper, the records of 700 cases of infantile paralysis treated in the Out Patient Department of the Massachusetts General Hospital were reviewed. Of 371 cases in which the onset was before the age of sixteen, 41 per cent had  $\frac{1}{2}$  inch or less of shortening, 24 per cent had over  $\frac{1}{2}$  inch but less than  $1\frac{1}{2}$  inches, and 35 per cent had  $1\frac{1}{2}$  inches or more of shortening (Fig 1)

It will be apparent that these figures give an abnormally high incidence of shortening. They pertain to patients in the Out Patient Department with sufficient residual crippling to warrant their seeking

FIGURE 2. Percentage of 371 Patients Developing Shortening of  $\frac{1}{4}$  Inch or More

medical help. In the poliomyelitis population as a whole the gross incidence of shortening must be considerably lower than the figures from this clinic.

#### Age at Onset

It will be obvious to the most casual observer that the age at onset must be an important factor in the production of discrepancy in leg length.

Adults who develop poliomyelitis can be expected to develop no discrepancy in leg length. But the infant, upon whom the growth retarding effect of poliomyelitis may act for the rest of his growing years, has a real chance of developing inequality in length (Fig 2 and 3).

#### Sex

Inequality in leg length of moderate or marked severity is more frequent in boys than in girls (Fig 4).

The growing epiphyses of the lower extremities close approximately two years earlier in girls than in boys. Therefore, the retarding effect of polio-

myelitis has a shorter time in which to act on the growing epiphyses of the former. Also the average adult leg length is less in the female than in the male, and therefore a percentage retardation of

FIGURE 3. Average Shortening in Inches among 371 Patients

growth should produce less actual discrepancy in length in the female than in the male.

#### Muscular Weakness

Discrepancy in adult leg length in poliomyelitis is practically invariably associated with asymmetrical

FIGURE 4. Shortening of Leg among 191 Female and 180 Male Patients

paralysis. In the cases under consideration no significant shortening was found in patients with symmetrical motor power. Whether the legs were totally paralyzed, partially paralyzed or normal, the

legs were essentially equal in length, provided the involvement was bilateral and symmetrical

The greatest amount of shortening occurred in cases in which there was one essentially normal leg and one totally paralyzed and in which the onset was at an early age. In every case in which there was one normal and one severely paralyzed leg, and in which the age at onset was under ten years, marked shortening occurred

#### *Amount of Shortening to be Expected*

No really accurate tables for the prediction of individual normal growth have been worked out. It is therefore improbable that an exact formula can be devised that will allow accurate long-range prediction of the amount of shortening to be expected in any given case of poliomyelitis. The multiplicity of variable factors affecting normal growth, in addition to those due to the disease, complicates the problem still further.

The growth curve for an individual patient is rarely smooth, since growth is not at a constant rate. Illness and health, use and disuse, winter and summer, and many other factors are involved.

In 1 case (Case 41402), in which poliomyelitis occurred at the age of five, the discrepancy in leg length, as indicated by clinical measurement, appeared to occur throughout the growing period. One leg was essentially normal in muscle power, and the paralyzed leg had about one third normal strength.

Both clinical measurements and teleoroentgenograms in another case (Case 60479) demonstrated that there was some shortening soon after onset, then the growth rate was essentially the same until about the age of thirteen, when the discrepancy increased, apparently owing to premature cessation of growth of the shorter leg. Measurement of teleoroentgenograms indicated that the shortening in this case was in both the femur and the tibia, but it may occur in the femur alone, in the femur and the tibia or in the tibia alone.

#### *Cause of Unequal Growth*

At one time a theory was proposed that the virus of poliomyelitis might directly affect one or more hypothetical growth centers in the central nervous system. No satisfactory evidence indicates that these growth centers exist, and the theory may be dismissed as extremely improbable.

The observed fact that unequal growth occurs only when there is unequal paralysis leads to the assumption that the relative amount of use of the two extremities is an important factor.

Another related factor is the circulatory status of the two extremities. Decreased circulation probably causes retardation, and increased circulation stimulation of growth of the involved extremity. Quantitative measurement of the circulatory status of the

extremities in poliomyelitis should prove to be a fruitful field for investigation.

#### *Equalization of Leg Length in the Adult*

The prevention and correction of discrepancies in leg length in poliomyelitis has engaged the interest of clinicians for many years. The methods of equalization of leg length available for adults are the use of a high sole, lengthening of the shorter limb and shortening of the longer limb. Adult discrepancies of less than  $\frac{3}{4}$  inch may, as a rule, be ignored. Occasionally, backache due to abnormal strain develops in these cases, requiring the use of a heel lift to equalize length.

Adults with moderate shortening ( $\frac{3}{4}$  to  $1\frac{1}{2}$  inches) usually require some shoe correction, whereas those with over  $1\frac{1}{2}$  inches of shortening almost invariably use a high sole to equalize length. The optimal amount of shoe correction depends upon a number of factors, which must be taken into consideration in each case. Complete equalization of length is rarely indicated, for the weaker leg, which is also the shorter one, is usually handled more easily if it is left slightly shorter. The clinician may estimate the amount of correction needed by placing blocks beneath the shorter leg as the patient stands barefoot. Sufficient lift is used to level the pelvis and to correct the list of the spine. The correction on the heel should be about  $\frac{1}{2}$  inch less, and the sole lift  $\frac{3}{4}$  to 1 inch less than the amount of lift necessary to correct the shortening completely.

#### *Leg Lengthening*

The first successful case of lengthening of the femur was reported in 1905 by Codivilla,<sup>9</sup> and additional cases were subsequently reported by Putu and Landini,<sup>10</sup> Abbott and Crego<sup>11</sup> and Compere.<sup>12</sup> But the operation is rather formidable and carries some risk of disaster from sepsis (osteomyelitis) and from delayed or absent union. The prolonged skeletal traction required is painful and necessitates several months of hospitalization. A full range of knee-joint motion after this operation is rarely obtained, and in a high percentage of cases, knee function is severely and permanently impaired. The operation of femoral lengthening was therefore soon abandoned.

Lower-leg lengthening (tibia and fibula) gradually supplanted femoral lengthening, and during the early 1930's enjoyed a considerable vogue. Abbott,<sup>11</sup> Wilson and Thompson<sup>14</sup> and others have used it successfully, most of the patients being children or young adults. Barr and Ober<sup>15</sup> reported a small series of cases in adults with good results. Lengthening of over 3 inches has been reported, but the average gain in length is 2 inches or less. This operation is subject to the same risks of sepsis and delayed union as femoral lengthening, and although knee-joint function is not appreciably affected, the ankle and foot are usually pulled into a deformed position (equinovarus), which requires operative

revision and stabilization of the foot in most cases. These and other problems make the procedure of leg lengthening one not to be embarked upon lightly. It is safe to say that the operation, once reasonably popular, is now rarely done.

### *Leg Shortening*

Shortening of the longer leg is the surgical alternative to leg lengthening in adults. Femoral shortening has been reported by several authors,<sup>14, 16-18</sup> and a number of variations in surgical technic have been proposed. The operation is not too difficult, the risk of sepsis and nonunion is less than that in leg lengthening, and the joint function is, as a rule, not impaired. The period of hospitalization and of disability is much less for femoral shortening than for leg lengthening. Femoral shortening in most clinics is now the operation of choice for equalization of adult leg length.

Shortening of the tibia and fibula is also a feasible method of equalization of leg length and has been performed in a small number of cases by Ober and by me. It is technically not so difficult as femoral shortening, and a leg cast only is required for post-operative immobilization, whereas femoral shortening requires a spica cast or suspension of the leg on a splint with the patient confined to bed. In 2 of my cases, there was marked postoperative swelling, with impairment of circulation of the foot, apparently owing to kinking of the blood vessels. Lumbar sympathetic novocain block and lumbar ganglionectomy may be of benefit if this complication occurs. The operation may prove to have advantages over femoral shortening.

Many patients and not a few surgeons are averse to major elective surgery on an extremity that is normal or nearly so. Though the procedure of leg shortening does not carry undue risk, it should be undertaken only after careful study of the problem by the surgeon and with the patient fully informed of the risks involved. Both the patient and the surgeon may accept the risk in the reasonable expectation of success. Freedom from a cumbersome, conspicuous, high sole is a goal worth striving for. The operation should be performed only if the weaker, shorter limb will be freed of all apparatus. If the patient must still wear a brace, little relative improvement is to be obtained by elimination of the high sole.

### *Equalization of Leg Length in the Growing Child*

The prevention of length discrepancy in the growing child has engaged the orthopedic surgeon's attention for many years, and today there is great interest in this problem. If a child has asymmetrical muscular weakness, what can be done to prevent or ameliorate the discrepancy in leg length that may be anticipated in such a case?

*Nonoperative measures.* So far as possible one should promote and maintain equal function in the

two legs. Full use of one limb and full immobilization of the other for prolonged periods should be avoided. In particular, prolonged plaster immobilization of the slower-growing extremity is harmful. The slower-growing limb should be dressed warmly and kept from chilling in cold weather, for it is logical to assume that there is an optimal temperature for growth of the epiphyseal plates.

*Operative measures.* The insertion of ivory pegs into or near the epiphyseal plates to stimulate growth was recommended and performed several decades ago without demonstrable beneficial effect. Similarly, juxtaepiphyseal drilling,<sup>19</sup> more plausible in theory, has proved disappointing on clinical trial and has been abandoned in most clinics.

Sympathectomy to stimulate growth was first proposed by Harris<sup>20, 21</sup>. If the operation is properly performed<sup>22</sup> the skin temperature of the affected limb is demonstrably raised, and the effect appears to be long lasting. In addition to the effect on growth, the cold, blue, lower extremity subject to excessive sweating, chilblains and ulcers is replaced by a warm, pink, dry lower extremity. The exact effect of sympathectomy on growth is difficult to assess in quantitative fashion. In 8 out of 9 cases in which sympathectomy was performed at the Massachusetts General Hospital, in an attempt to stimulate growth, the rate of growth of the affected limb kept pace with or actually exceeded that of the opposite limb. In only 1 of 4 cases has increased shortening occurred after sympathectomy. End-result studies on a larger series of cases are needed before final conclusions can be drawn, but this operation holds promise of being of real value. It is essentially without risk, hospitalization is short, and convalescence is rapid. It cannot be expected to be of much benefit if marked shortening has already occurred or if the operation is done after the age of twelve or thirteen. The young child with marked paralysis of one extremity and a nearly normal opposite extremity is a good candidate for this operation, particularly if the affected limb is cold and blue, perspires freely and is subject to chilblains.

Retardation of growth of the longer leg by operative arrest of growth of one or more epiphyseal plates (epiphyseal arrest, or epiphyseodesis) was first proposed by Phemister.<sup>23</sup> Several authors have reported series of cases in which the operation has been done and have discussed selection of cases, operative technic and end-results.<sup>19, 24, 25</sup> The epiphyseal plates most commonly fused are those near the knee joint—that is, those of the lower femur and the upper tibia and fibula. There is no doubt that the operation effectively retards growth. If the lower femoral epiphyseal plate contributes approximately 40 per cent and the upper tibial 25 per cent of the total leg length, fusion of these

two growth centers should retard further growth of the extremity by 65 per cent. But numerous difficulties arise in connection with this procedure. There is no accurate method of long-range prediction of the final discrepancy in leg length that would occur if no corrective measures were instituted. Until a satisfactory method of growth prediction is evolved, the age at which epiphyseal arrest should be done cannot be accurately estimated. White and Warner,<sup>25</sup> Gill and Abbott,<sup>6</sup> Straub, Thompson and Wilson<sup>24</sup> and Green and Anderson<sup>4</sup> have worked out methods of predicting the retarding effect of epiphyseal arrest on growth. The method of Green and Anderson has the virtue of simplicity, since the amount of retardation of growth to be obtained by epiphyseal arrest at any given skeletal age may be read directly from a chart. The operative technic of epiphyseal arrest consists in excising medial and lateral portions of the epiphyseal plate and replacing them with bone blocks, which extend into both the epiphysis and the diaphysis. An operative procedure that the authors consider satisfactory is described in detail. Not all surgeons have found the operation either easy to perform or uniformly successful in outcome. Deformities of the knee (valgus, varus and recurvatum) were noted in 6.5 per cent of cases reported by Green and Anderson<sup>4</sup> and in 11 per cent of those reported by Wilson and Thompson<sup>14</sup> and Regan and Chatterton.<sup>26</sup> Almost 10 per cent of the series of Green and Wilson required secondary operation because of deformity or lack of effective fusion of the epiphyseal plate or for arrest of the opposite side because of overcorrection.

Nevertheless, epiphyseal arrest is a method of proved success. It can be expected to equalize discrepancies in length of considerable magnitude. Careful consideration must be given to proper case selection. The correct age for operation and the epiphyses to be fused must be carefully determined. The operation must be meticulously performed. Attention to these factors will ensure that approximately 90 per cent of the patients will reach adult life with shortening of no clinical significance.

*Irradiation to retard longitudinal growth.* For a number of years Barr and his associates<sup>27, 28</sup> at the Massachusetts General Hospital have carried on experimental work on animals as a preliminary to the clinical use of irradiation. This work indicates conclusively that x-ray irradiation of the growing epiphyseal plates of the rat and the dog produces definite retardation in longitudinal growth. Single doses of 800 to 1200 r were effective, and the retardation was roughly proportional to the dosage employed. The maximal retardation in growth of an individual epiphysis was about 80 per cent, but the retarding effect was lessened by an overgrowth of adjacent, untreated epiphyses. The net maximal retarding effect on growth of an individual bone by treatment of one epiphysis was about 30 per cent.

Histologic examination revealed no evidence of damage to skin, subcutaneous tissues, muscle and bone. The articular cartilage, though normal to gross examination, showed mild but definite microscopical changes indicative of cellular damage. The clinical use of x-ray irradiation to prevent shortening or to equalize discrepancies in length already acquired must be considered to be in the experimental stage. It holds definite promise, however, and may prove to be a useful and effective method.

### SUMMARY

Normal growth is influenced by many hereditary and environmental factors, which determine the size and shape of limbs. It is extraordinary that symmetrical limbs of equal length are the rule and not the exception.

The causes of unequal growth of the legs, resulting in shortening, are discussed, with particular attention to poliomyelitis.

The exact incidence of leg shortening due to poliomyelitis is not known, but approximately a third of the patients with poliomyelitis treated in the Out-Patient Department of the Massachusetts General Hospital with onset before the age of sixteen developed marked inequality in leg length. The factors of importance in determining whether a patient will develop discrepancy in leg length include age at onset, sex and the amount and distribution of muscular weakness of the legs. There will be no shortening if the involvement is symmetrical. The greatest shortening occurs in young patients with one normal and one severely paralyzed limb.

Inspection of growth curves of individual cases suggests that the growth retardation is not constant. The maximum retarding effect appears in some cases to occur late in the growing period. Premature cessation of growth associated with epiphyseal closure on the paralyzed side may explain late occurrence of severe discrepancies. Exact prediction of the amount of shortening to be expected in a given case is not yet possible. The possible causes of unequal growth in poliomyelitis include changes in circulation and disuse of the extremity.

Operative correction of adult discrepancy in length is possible by leg-lengthening or leg-shortening procedures, the latter appear to be preferable.

In the growing child epiphyseal arrest offers a method of equalization that in properly selected cases is very effective. Careful attention must be given to the proper age for intervention and to the operative technic.

Sympathectomy as a procedure to maintain equality in leg length is still *sub judice*, but it appears to be of value if done early enough.

Every growing child with poliomyelitis should be under the regular supervision of an orthopedic surgeon who is thoroughly familiar with the problem of unequal growth. Regular measurement of the

leg length, clinically and by x-ray examination, will allow early detection of shortening. The surgeon by suitable selection of operative methods and by promotion of normal function in the affected extremity will be able to prevent much of the shortening that would otherwise occur. The unsightly cork or wooden high sole should become a much less familiar sight. Eventually the time may come when no child will need to face adult life with that handicap.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

### Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

### CASE 34211

#### PRESENTATION OF CASE

A fifty-six-year-old engineer was admitted to the hospital because of pain in the right side and difficulty in breathing.

Approximately six months before admission the patient developed a cough productive of "white mucus," but had no other symptoms. Seven weeks before admission he awoke one morning with a severe pain in the right lower chest, which was made worse by breathing. Records from the hospital in which he was treated stated that there were physical and x-ray findings of a pulmonary infarct. He was given penicillin and dicumarol

During the hospital stay he became violent and developed delusions of persecution. After three weeks of hospitalization he was discharged but was never free of chest pain. Later, this became worse and was aggravated by breathing. Two days before entrance to this hospital an x-ray film taken at another hospital was reported as showing "a large abscess cavity in the right subdiaphragmatic region and a right-sided pleuritis." He lost approximately 35 pounds in the course of the illness.

The patient had had a "double coronary" seventeen months before admission. He had had occasional ankle edema and slight exertional dyspnea since then.

Physical examination revealed a man with somewhat grandiose ideas and with some difficulty in thinking of words. The chest was emphysematous with expansion limited by pain. There was dullness over the lower third of the right chest posteriorly. The right leaf of the diaphragm was elevated and limited in excursion. Breath sounds and vocal fremitus were diminished over the right lower chest. A friction rub was audible posteriorly near the right base. The liver edge was palpable three fingerbreadths below the costal margin and was tender.

The temperature was 99°F, the pulse 120, and the blood pressure 110 systolic, 80 diastolic.

Examination of the blood disclosed a hemoglobin of 12.2 gm and a white-cell count of 16,700, with 89 per cent neutrophils. The urinary sediment contained a rare white cell. The sputum was negative for acid-fast organisms.

An x-ray film showed questionable fluid over the lower half of the right chest. The middle lobe was collapsed. There was a fluid level with an air space above it at the right base. The right leaf of the diaphragm could not be identified, since it did not move with respiration. The left lung field was clear. An electrocardiogram showed low voltages and probable right-axis deviation. In addition, in the chest leads the S waves were prominent, and the R waves small to absent.

The patient was prepared for a thoracotomy on the second hospital day. Quinidine (0.15 gm) was given one hour before operation. A short time after the intratracheal tube had been inserted the patient stopped breathing, and no pulse could be obtained. Attempts at resuscitation were unsuccessful.

#### DIFFERENTIAL DIAGNOSIS

DR F DENNETTE ADAMS: One must consider the entire gamut of subacute and chronic pulmonary diseases: tuberculosis, abscess, bronchiectasis, foreign body, actinomycosis and others. However, the evidence in this case seems typical, if one can say anything in medicine is typical, of bronchiogenic carcinoma. The illness started with cough, virtually nonproductive, for four weeks. There were no other symptoms except quite rapid loss of weight. Then an acute episode occurred—fever and pain in the chest. The record from the other hospital states that the patient had typical signs and x-ray findings of pulmonary infarction. One hesitates to be critical, and yet it should be pointed out that this is a broad statement.

Pulmonary embolism presupposes thrombophlebitis or phlebothrombosis. If the patient was up and around, phlebothrombosis would not be likely, if he had thrombophlebitis, he would have in all likelihood signs in his legs. So there is very little ground for presupposing trouble in the veins unless one wishes to assume that it was there because of the presence of a malignant lesion elsewhere. In my opinion, one cannot say that either the physical or x-ray signs were necessarily typical of pulmonary infarction. Similar signs may occur in collapse and in pneumonia. Furthermore, when the signs appear with pulmonary embolus in the lungs they have to be due to a fairly large embolus, and in such a case one would expect at the onset some signs of temporary insult to the circulation. This patient apparently had no such episode. I am much more inclined to believe that the trouble was infection: pneumonia or, if my original assumption is correct, more probably secondary infection behind complete obstruction of a bronchus. Another

good reason for believing that this was not a pulmonary infarction is the fact that the pain continued, the patient with pulmonary infarction recovers rapidly unless more emboli form.

This man continued to be sick, to have pain and to lose weight. He came into the hospital with grandiose ideas and difficulty in thinking of words. We shall come back to this in a moment. The signs in the chest on admission to this hospital could have been due to almost any form of pulmonary disease: low-grade infection, thickened pleura, fibrosis or collapse or a combination of these. The statement that the right leaf of the diaphragm was elevated cannot be made if other recorded physical signs were correct. With dullness and diminished respiratory sounds the diaphragmatic movements could not be determined accurately. The patient still had a friction rub. We can assume that he had it all along because of the pleural type of pain. The white-cell count indicated a suppurative form of infection, and this was borne out by the x-ray film, which showed a pulmonary abscess. This could be secondary to pneumonia, bronchial obstruction from foreign body, tumor or other cause or to infarct.

My belief is that in a man of fifty-six with this history and the disease taking the course described, one is justified in making almost a flat-footed diagnosis of bronchiogenic carcinoma with obstruction and secondary infection.

Will Dr Wyman demonstrate and discuss the films for me?

DR STANLEY M WYMAN: There seems to be definite fluid along the lateral margin of the right chest. The right leaf of the diaphragm cannot be identified laterally, but there is a suggestion of the diaphragm medially, and a large cavity containing air and fluid. A definite fluid level is seen in the midlower portion of the lower lung field, which lies posteriorly in the lateral view. The right lower lobe appears to be diffusely consolidated and perhaps slightly decreased in size. I cannot identify the collapse of the middle lobe described.

DR ADAMS: Is the lung pulled over a little?

DR WYMAN: It does not seem so to me. The chest is rotated slightly. The spine in its midportion lies here to the left so that this appearance might be due to the rotation of the patient on the film. I can identify the left main bronchus fairly well. The right main bronchus I can follow only down to about 3 cm beyond the bifurcation. I cannot make out a definite mass, but there is a suggestion of some hazy density overlying this portion of the hilus, with a poorly defined lateral border.

DR ADAMS: I am still going to stick to the diagnosis already made. The best bet in a man of fifty-six years, who has cough for several months, then develops an abscess and meanwhile loses weight and goes downhill, is a malignant lesion of a bronchus, with obstruction and secondary infection.

As I read over this record, I wondered about the haste in operating. The patient came in one day and was prepared for operation on the next. He was not bronchoscoped. Little attention seems to have been paid to what appears to have been a significant factor when the man was in another hospital several weeks previously he was paranoid, and while in this hospital he had obvious personality changes. The degree of fever is hardly sufficient to account for so much personality change. No studies were done to try to determine its cause. One cannot exclude a psychosis unrelated to the rest of the picture, and yet that seems no more than tenable. The patient could have had general paresis, but we have no evidence at all. He could have had — and this merits particular emphasis — a drug psychosis, a disturbance often overlooked because not thought of. He had pain for a long time. We do not know what medication he was getting. He may have been filling himself up with bromides or barbiturates. I have recently seen 2 cases of bromide poisoning resembling this picture. The other possibility, and the one that seems to me most likely, is a metastatic lesion in the head, either carcinoma or abscess. One cannot distinguish between the two, but on general principles, if my basic diagnosis is correct, metastatic cancer seems more likely than abscess.

What was the cause of death? The patient was known to have had a coronary infarction. The electrocardiogram showed low voltage, suggesting a poor myocardium or, less likely, pericardial disease, perhaps spread of the tumor into the pericardium. The changes in the R and S waves suggest the possibility of residua of old coronary-artery disease. One cannot state that the sudden death was not due to heart failure. Certainly, the small dose of quinidine cannot be held responsible. On the other hand, we must remember that the patient had been subjected to some manipulation while the intratracheal tube was being inserted, and I think that he may have died of a pressure cone although this is really not much more than a guess. Since a diagnosis must be ventured, I am going to commit myself to carcinoma of the bronchus with secondary infection of the lung due to bronchial obstruction, metastatic carcinoma of the brain and death from a pressure cone.

DR DONALD S. KING Are you sure that the process is not below the diaphragm, Dr. Wyman?

DR WYMAN No, I am not sure by any means. I think that I can outline the right leaf of the diaphragm medially and also in the lateral view anteriorly. I cannot be sure but I think that it is above the diaphragm.

DR JOHN QUINCY Do you think that there is some emphysema on the left?

DR WYMAN The films are overexposed to bring out the details in the right lung, making accurate statement about the left lung difficult. However, there is some emphysema on the right side.

DR ADAMS That could be explained on the basis of compensation.

DR WYMAN Yes, there is a little compensatory emphysema in the upper lobe on the right side.

DR ADAMS The patient had an overdistended lung base. We know that he used that lung more for the air that he needed.

DR WYMAN It is not a process of long standing, however, and the anteroposterior diameter of the chest is not significantly increased.

DR CARROLL C. MILLER I saw this patient in another hospital before he was admitted to the Baker Memorial. At first sight he was a very sick man and obviously not getting better. The local physician and I could not make a definite diagnosis. X-ray films taken in the other hospital were perhaps more equivocal than ours are in determining the location of the diaphragm, and we did not know whether the abscess cavity, this air-filled pocket with fluid in it, was below or above the diaphragm. The patient was mildly confused in his thought processes, and it was difficult to get a clear-cut, consecutive story from him. The history showed no evidence of drug toxicity. He had been followed for several months in a hospital in the Midwest and later at this local hospital. It was thought that drugs did not enter into the picture. He had had a definite change of personality and at one time had threatened his wife.

DR ADAMS Are you sure that was not routine?

DR MILLER That was a definite change. I had him admitted to the Baker Memorial, and because of improvement in his mental status at the time, this did not seem to be a problem. Because of the fact that he was running a spiking temperature Dr. Richard H. Sweet decided to drain the area as soon as possible. We had entertained the possibility that the process was a subdiaphragmatic abscess, and it was rather difficult to make sure that he had not had a ruptured ulcer because he had had vague upper abdominal fullness within the past year. That added to the confusion in trying to determine whether the lesion was above or below the diaphragm. The physical findings on admission here were the same as those at the other hospital — diminished breath sounds with rales at the right base.

In reference to your remark about confinement to bed, he was immobilized for a considerable period in a hospital in the Midwest during the episode of coronary-artery disease.

DR ADAMS That had been eighteen months before, however.

DR MILLER Yes, a long time before. The possibility of infarcts with subsequent breakdown and abscess formation within the lung occurred to all of us. The picture did not appear like a clear-cut lung abscess to us. There was no foul-smelling sputum during the course of the disease, and the cough seemed not to be a major problem. It was not

the typical cough that accompanies carcinoma of the bronchus, which is more commonly an irritative one. Of course we had had in the back of our minds carcinoma of the lung, not infrequently we see such cases without typical symptoms.

A word about the anesthesia—it was entirely uneventful. During the induction of anesthesia the patient was quite dry, and there was no appreciable amount of struggling. He simply stopped breathing just as he was to be taken into the operating room and could not be revived.

#### CLINICAL DIAGNOSES

Coronary occlusion  
Subdiaphragmatic abscess?

#### DR ADAMS'S DIAGNOSES

Bronchiogenic carcinoma, with metastasis to brain  
Secondary lung abscess  
Pressure cone

#### ANATOMICAL DIAGNOSES

*Empyema, right pleural cavity*  
Coronary sclerosis, with occlusion  
Infarct of heart  
Emphysema, moderate

#### PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Autopsy showed that the cavity was above the diaphragm and was entirely within the pleural cavity, a large encapsulated empyema. We were not able to identify any intrapulmonary lung abscess. There remained the possibility, of course, that there had been a small intrapulmonary abscess that had ruptured into the pleura and had been the source of the empyema. The old coronary-artery disease was sufficient to have caused complete occlusion of the descending branches of the left coronary artery and a very large area of infarction at the apex of the left ventricle, running halfway up the interventricular septum. This was covered by a thick partially organized thrombus. There was no evidence of cancer, and no lesion could be found in the brain—abscess, infarct or tumor.

DR ADAMS Why did the patient die?

DR MALLORY I cannot explain the mechanism. He had the type of heart with which a patient could die instantly.

## CASE 34212

### PRESENTATION OF CASE

A fifty-three-year-old hospital employee was admitted to the hospital complaining of nausea, vomiting and diarrhea.

His employment at the hospital began two months before admission. A routine examination was negative. The heart and lungs were within normal limits on physical and x-ray examination. The blood pressure was 140 systolic, 88 diastolic. A routine urine examination demonstrated an acid urine, with a specific gravity of 1.018 and the absence of sugar and albumin. A microscopical examination of the urinary sediment was not done. Two weeks before admission the patient began to feel "logy," vaguely sore between the shoulder blades and chilly (without frank chills). On the next day he lost his appetite and noticed that his throat was sore. He became nauseated, vomited all food and liquids ingested, including water, and began to have watery bowel movements, up to four or five a day. These complaints continued up to admission. One week before admission dyspnea on climbing one flight of stairs appeared. He had never had any dyspnea previously. There was no orthopnea. He had a slight tickling cough, productive of small amounts of whitish sputum. A week before admission he blew a clot of blood from his nose, but he insisted that he had not actually coughed up any blood. On the day before admission the nasopharynx was injected, general physical examination was otherwise not remarkable, and he was afebrile. A chest film demonstrated cardiac enlargement, with pulmonary congestion and a small right pleural effusion (Fig 1).

The only previous illness he could recall was an attack of "asthma" about six years before entry, which subsided without treatment.

Physical examination revealed that the patient was not acutely ill, but was somewhat pale, the tongue was dry, and the throat was beefy and a little edematous. The superficial veins of the neck were distended 1 or 2 cm above the clavicles in the semierect position. A few, moist, inspiratory rales were present at both lung bases, and there was some dullness over the right base. The heart was slightly enlarged to percussion. No murmurs were present. The sounds were distant and of poor quality, but no gallop rhythm was heard. The liver

edge was percussed 3 cm below the right costal margin. There was slight tenderness to percussion in both costovertebral angles, more on the right than on the left. The prostate was very slightly enlarged. There was slight pitting edema over the ankles. No calf tenderness was present.

The blood pressure was 185 systolic, 95 diastolic.

Examination of the blood disclosed a red-cell count of 3,200,000, with a hemoglobin of 11 gm per 100 cc, and a white-cell count of 9900, with 86 per cent neutrophils. The specific gravity of the urine varied between 1.015 and 1.022, and there was a +++ test for albumin. Repeated examinations of the urinary sediment demonstrated between 5 and 15 red cells and between 20 and 50 white cells per high-power field. Many hyaline, granular and red-cell casts were found. The fasting blood sugar was 113 mg., the nonprotein nitrogen 100 mg., and the total protein 6.6 gm per 100 cc. The carbon dioxide was 17.7 milliequiv., and the chloride 104 milliequiv per liter.

Three hours after admission to the Emergency Ward and thirty minutes after arriving on the hospital ward the clinical condition changed dramatically, and severe, acute, pulmonary edema appeared. Therapy included morphine, oxygen by mask, intravenous cedilanid and amioephyllin. An initial response to this treatment was favorable, but a picture of pulmonary edema continued. On the second hospital day there was distinct mental confusion, with mumbling and lapses of memory. On the next day the nonprotein nitrogen was 125 mg., the calcium 8.2 mg., and the phosphorus 7.5 mg per 100 cc. The chloride was 110 milliequiv., and the carbon dioxide 18.9 milliequiv per liter. The patient died that day.

#### DIFFERENTIAL DIAGNOSIS

DR BRIANT L. DECKER: May we see the x-ray films? Have you the old films?

DR STANLEY M. WYMAN: No, they are not available. In this recent series of films the heart shadow cannot be adequately outlined, but it seems to extend farther to the right and left than is normal. The heart, although it cannot be well seen, is probably enlarged. There is a definite pleural effusion on the right obscuring the costophrenic angle. The diaphragm is elevated, with localized effusion in the minor septum between the right

upper and the middle lobes. There is probably some fluid on the left, although that cannot be stated with certainty. The pulmonary vascular shadows of both hili are definitely increased. This increased prominence extends fairly well out into both lung fields peripherally. One cannot see any definite intrinsic localized pulmonary disease. There

FIGURE 1

is nothing specific that one can say about the configuration of the heart.

DR DECKER: Do you believe that the hili are consistent with congestive failure?

DR WYMAN: Entirely consistent with congested arteries, but the possibility of nodes in one or both hili cannot be excluded. This might be determined by fluoroscopy, one cannot exclude nodes from the films alone.

DR DECKER: In summary, we have the history of a fifty-three-year-old man whose only known previous illness was an attack of asthma six years before admission, the details of which are not given. He was in apparently good health until two months before admission except for the possibility of slight hypertension. For two weeks before admission he had symptoms of acute infection localized in the pharynx, but he also had gastrointestinal symptoms. One week after the onset of this infection he de-

veloped symptoms of congestive failure, and on admission to the hospital, examination showed acute pharyngitis, fairly marked hypertension and signs of both right-sided and left-sided cardiac failure. Laboratory tests revealed a slight normochromic anemia, a high normal white-cell count, with a fairly marked neutrophilic reaction, a urine typical of, or rather consistent with, acute glomerulonephritis and blood chemical findings indicating a nonprotein nitrogen retention and moderate acidosis. Although the patient did not appear very ill on admission, he shortly afterward developed severe acute pulmonary edema, which responded poorly to treatment. Within twenty-four hours he developed mental confusion and within forty-eight hours died, I believe of congestive failure.

Of the possible explanations of the history the first condition that comes to mind is acute glomerulonephritis. The patient was older than is usual with that condition, but there have been at least 2 cases of acute glomerulonephritis in elderly patients reported here in the past year. I must assume that the onset of the nephritis was coincident with or very shortly followed the acute throat infection. This is not very usual. It is possible and even probable that the onset of the initial infection that caused the acute glomerulonephritis was unnoticed, and that the symptoms that were evident two weeks before admission — nausea and vomiting, particularly — indicated the onset of renal failure and nitrogen retention. It is not unusual for a patient with acute glomerulonephritis to go into uremia as quickly as this patient apparently did, but in a small percentage of these cases that happens. More often the patient develops hypertensive encephalopathy, with marked cerebral symptoms and convulsions. These symptoms are not dependent on a high nonprotein nitrogen. In this case, however, the nonprotein nitrogen was considerably elevated and rising, and there was a low serum calcium, an elevated phosphorus and a decreased carbon dioxide — all characteristic of uremia. The cerebral symptoms were only moderate, and there were no convulsions.

An acute flare-up of chronic pyelonephritis or an initial onset of acute pyelonephritis seems unlikely to me because of the absence of typical symptoms — chills, a febrile course and so forth — of characteristic urinary findings. I believe that the finding of casts, particularly the red-cell casts,

is against pyelonephritis. For similar reasons bacteremia with an acute focal nephritis does not seem tenable. However, another condition that might well explain the whole picture is periarteritis nodosa. This usually affects younger persons but may occur at any age. It is usually of weeks' duration, runs a febrile course and is almost invariably associated with, or follows, an acute infectious process. The febrile course was not evident in the case under consideration, but the period of observation was brief. Renal lesions are present in a high percentage of these cases, — about 80 per cent, — and frequently these are suggestive of acute glomerulonephritis, with accompanying renal failure. Cardiac involvement is likewise very frequent. The symptoms of periarteritis nodosa may be so varied that it is a very convenient condition to mention in these discussions. It is rather difficult for me to decide between these two conditions, but on the basis of probabilities it is my opinion that this man had acute glomerulonephritis. It may have been associated with periarteritis nodosa, but that is my second choice. I believe that he died of congestive failure and had uremia.

DR LINCOLN CLARK. I can add a few details. During the last day the patient developed a paranoid psychosis. He believed that we were trying to poison him, refused medication and became belligerent and combative. I examined him but could find no change from the previous day. The nurse called me because he had refused to take penicillin. He was wildly thrashing around and snatched the stethoscope from me. Five minutes later he was dead. The examination of the chest, so far as it could be accomplished, revealed the clinical findings of pulmonary edema with markedly diminished respiratory exchange. The psychotic episode was probably the preliminary phase to the pulmonary edema of which he died.

DR TRACY B MALLORY. Does no one want to suggest a lower-nephron nephrosis? Patients with that condition commonly die of acute pulmonary edema, and it is statistically becoming more frequent than glomerulonephritis. There are two points in the history that are strongly against it. One is the specific gravity of 1.022, which would be very much higher than one would expect, the other is the red-cell casts.

DR WYMAN. From the x-ray point of view pulmonary edema, vascular congestion and pleural

effusion are all present. This may be associated with nephritis and might be the result of it. One would have to suppose that the patient had pre-existing or co-existing heart disease because of the degree of cardiac enlargement.

DR MALLORY That film was taken the day before the clinical evidence of pulmonary edema developed.

DR WYMAN Yes, he already had x-ray evidence of edema at that time.

DR DECKER I considered the possibility that the attack of asthma six years previously was really an attack of acute pulmonary edema, indicating a damaged heart then, and that this superimposed elevation of blood pressure, uremia and so forth, was enough to produce this picture. That is one reason why I wanted to see the old x-ray films to determine if at that time the heart was borderline in size.

#### CLINICAL DIAGNOSES

Acute pulmonary edema

Uremia due to nephritis,

unknown cause, and to

cardiac insufficiency of two weeks' duration

#### DR DECKER'S DIAGNOSES

Acute glomerulonephritis

Uremia

Congestive failure

#### ANATOMICAL DIAGNOSES

*Acute glomerulonephritis*

*Chronic vascular nephritis, slight.*

*Acute pulmonary edema.*

Hypertrophy and dilatation of the heart, hypertensive type

Hydrothorax, bilateral

#### PATHOLOGICAL DISCUSSION

DR MALLORY At autopsy we found enlargement of the heart and the kidneys. The heart weighed 460 gm. The coronary arteries were in very good condition, and there were no valvular lesions so that we are forced to assume that there had been a hypertensive heart disease of considerable standing.

The kidneys were very much enlarged, they weighed 500 gm. The capsule stripped with difficulty, leaving a pitted surface that suggested underlying renal disease of long standing, but the microscopical sections showed an extremely acute glomerulonephritis. I think it was superimposed on a slight chronic vascular lesion, which probably had been present for many years. The fresh episode is very characteristic of acute glomerulonephritis, and could not possibly be confused with the so-called "malignant phase" of vascular nephritis. The fatal episode of acute pulmonary edema is not the usual mode of exit for these cases with a non-protein nitrogen still as low as 120 mg per 100 cc. We saw death from pulmonary edema very frequently in crush and shock kidneys during the war, but in most of those cases the picture was complicated by a great deal of parenteral fluid, which was not given to this man. Consequently, the pulmonary edema in this case was not brought on by treatment. I am inclined to attribute it to acute heart failure rather than to renal failure.

DR ALFRED KRANES What was the urinary output during observation?

DR MALLORY The patient was in the hospital for such a short time that it is not known.

## "A PATTERN FOR CHILD HEALTH"

THE country-wide study of child-health services, launched in March, 1946, by the American Academy of Pediatrics at the successful conclusion of the pilot study in North Carolina, has been finished. Detailed state by state reports and recommendations are being prepared, the national report will be issued this summer.

The findings of this million-dollar study, financed by the Academy, the federal Government, various foundations, business firms and state organizations were entirely predictable although never before specifically stated. Adequate pediatric care, according to the preliminary reports, does not reach the people, effectively distributed. Isolation from the

potential benefits of good medical practice prevails for individuals, for families, for communities and for economic levels of society, the result of geographic and economic factors and of ignorance.

Erratic failures to balance supply and demand persist. There are not enough doctors in practice where doctors are most needed, and too many flock to those communities or sections where better facilities for practice may exist, or where the economic level of the population is higher. In some communities the doctors are available but hospital beds are lacking, in others the beds are available but the doctors are absent. It may be said that in general the pediatric training of physicians is inadequate. Unavailable medical care in the country and failure to utilize available medical care in the city are still responsible for many child deaths. In various aspects relating to health promotion we have even fallen behind some of our progressive neighbors such as Canada and the Scandinavian countries.

Once a diagnosis has been established and accepted the way is open for any possible therapy to be applied, and in this instance the disease is definitely curable. A network of medical services must be developed to cover every community, with hospitals, clinics, health services and physicians. The services of the metropolitan centers must be made to flow out to the rural hospitals. The training of young physicians must be improved to the point that all those in general practice, as well as the pediatricians themselves, will be equipped to give good child care.

The American Academy of Pediatrics has done a splendid piece of work in carrying through this ambitious program of fact-finding. Its business and that of all associated agencies will now be to work toward the proper application of the obvious remedies.

## FOUR HUNDRED AND THIRTY YEARS AGO

WE ARE so frequently impressed by the recent advances in scientific medicine, so pleased that we can rightly speak of milligrams and correctly determine the hemoglobin to a fraction of a percent — by machine let it be said — that we are prone to forget that our forebears, without so much as a

hlet or Technicon, laid the firm, substantial foundations on which we build today. Lakin's\* Harveian Oration of 1947 recalls our debt to mind.

Our own Association of American Physicians, of which we are justly proud, was founded in 1886 by such men as "Popsy" Welch and Dr. Councilman, known to all as "Councv." Such men as these, the founders and benefactors of our Association, have rightly earned the admiration and respect that is their due.

The British counterpart of this society, its father and mother so to speak, was the Royal College of Physicians founded nearly four hundred years earlier — in 1518 to be exact.

"In the year 1345 King Edward the third had allowed a pension of sixpence a day to Coursus de Gangland, an apothecary of London, for his attendance during his illness. Yet during the fourteenth and fifteenth centuries medical knowledge was at a very low ebb, and "The Peterhouse chained library of 1418 held but thirteen volumes of medicine," among which was the notable work of "Richard of Wendover (ob. 1252), canon of St. Paul's, the compiler of an encyclopedic treatise covering the entire field of medicine. "The one fellow of Cambridge allowed by statute to adopt the medical art was pursuing in 1418 the regular university course, he had borrowed Macer, *De Virtutibus herbarum* and the prescribed texts of Johannicus and of Isaac." When we recall that Johannicus was none other than Honein ibn Ishaq el 'Ibadi, that he died in the year of our Lord 873, and that "Isaac fuit arabs nacione" we realize that medicine then was surely in a sorry state.

Yet only one hundred years later, during the reign of Henry the Eighth — he of the elastic conscience — there was founded the Royal College of Physicians by Thomas Linacre, the Greek and Latin scholar who is said to have introduced the damask rose into England not long before he died in 1525.

There is no direct, unbroken line by which we may connect the medical practice of the ancients with that of the modern day. But it seems certain that during the Dark Ages Arabic medicine was supreme and that the most important results of the revival of learning in the fifteenth and sixteenth centuries

were the accurate translations from Greek into Latin of the great masters such as Hippocrates and Galen. Among the very foremost of these translators was Thomas Linacre, founder and benefactor of the Royal College. The revival of Hippocratic and Galenic medicine did not immediately produce any important reform in practical medicine, but the great outbreak in England of the "sweating sickness," described so well by John Kaye or Cains, a successor of Linacre, and the appearance of syphilis, seemingly unknown to the Greeks, made it clear that the works of Galen did not contain all that could be known of medicine. Thus were physicians of that day urged on to make their own observations and to a keener attention to the natural history of disease. As early as 1649 the hitherto undescribed rickets was carefully studied by Arnold de Boot, a practitioner in Ireland. From this point it is but a short step to Thomas Sydenham and thence to the great systemizers of medicine — Cullen and Brown. Medical knowledge seemed to wane at the end of that century but received new life from Auenbrugger and Laennec and from that time on with such minor alarms and excursions as the expressed belief of Hahnemann (1753-1844) that "Seven-eighths of all chronic diseases are produced by the itch driven inwards," progress in medicine has been steady until, today, we can speak of millimoles and the MCHC — whatever that may be.

Yet when all is said let us not forget the founders and benefactors of the Royal College, for they and their peers started us on our journey into the Golden Age of medicine from the Dark Ages when doctors were but pompous charlatans and when "If a poor man speke a word he shal be foul affronted."

## HYGEIA VERSUS PANACEA

As a reminder that the rehabilitation clinic is not a new idea, Miss Hazel Newton, general manager of The Community Workshops, has written a comprehensive letter that is published elsewhere in this issue of the *Journal*. War, with its hideous casualty lists, has swelled the ranks of the handicapped to a point where publicity is being focussed on their needs, the Community Workshops, in a very unassuming way, has been operating in the field of rehabilitation for over seventy years.

# NEW ENGLAND ALUMNI OF BALTIMORE MEDICAL COLLEGE, COLLEGE OF PHYSICIANS AND SURGEONS AND UNIVERSITY OF MARYLAND MEDICAL SCHOOL

The annual luncheon meeting of the New England alumni of Baltimore Medical College, College of Physicians and Surgeons and University of Maryland Medical School, will be held at the University Club, 40 Trinity Place, Boston, on May 26, at 12 30 p m. The section meetings and exhibits of the three-day annual meeting of the Massachusetts Medical Society at the Hotel Statler, beginning on May 25, will be open to visiting alumni. Reservations should be made before May 17 to the secretary-treasurer, Dr Charles E Gill, 184 North Street, Pittsfield, Massachusetts.

## NEW ENGLAND HEALTH INSTITUTE

The 1948 New England Health Institute will be held at the University of Massachusetts campus at Amherst on June 16, 17 and 18. Programs have been mailed to five thousand local and state health-department workers in the six New England states.

Panel discussions on advances in local health services, chronic illness and health needs of children will be supplemented by the varied topics on the five section meetings arranged for June 17 by the Massachusetts Public Health Association.

At special dinner meetings on June 16 and 17 addresses by Dr Leonard A Scheele, surgeon-general of the United States Public Health Service, and John H Crider, editor-in-chief of the *Boston Herald*, will be presented.

## NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

A meeting of the New England Society of Anesthesiologists will be held in the Bigelow Amphitheater of the White Building, Massachusetts General Hospital, Boston, on Tuesday,

June 8, at 8 p m. A scientific program will be presented by the Rhode Island Hospital group.

## PROGRAM

Fluid Therapy Russel O Bowman, Ph D

Anesthesia for Hip-Nailing E F Neves, M D, and Margaret Iszard, M D

Some Considerations of Endotracheal Anesthesia Clement S Dwyer, M D, and Sanford Kronenberg, M D

Physicians and medical students are invited to attend

## NATIONAL CONFERENCE OF COUNTY MEDICAL SOCIETY OFFICERS

The third National Conference of County Medical Society Officers will be held at the Palmer House, Chicago, on June 20 from 10 a m to 4 p m.

Although the program is directed primarily to officers of county medical societies, any member of the American Medical Association is welcome to attend and participate in the discussion.

# SHOULD VITAMIN D BE GIVEN ONLY TO INFANTS?

**V**ITAMIN D has been so successful in preventing rickets during infancy that there has been little emphasis on continuing its use after the second year.

But now a careful histologic study has been made which reveals a startlingly high incidence of rickets in children 2 to 14 years old. Follis, Jackson, Eliot, and Park\* report that postmortem examination of 230 children of this age group showed the total prevalence of rickets to be 46.5%.

Rachitic changes were present as late as the fourteenth year, and the incidence was higher among children dying from acute disease than in those dying of chronic disease.

The authors conclude, "We doubt if slight degrees of rickets, such as we found in many of our children, interfere with health and development, but our studies as a whole afford reason to prolong administration of vitamin D to the age limit of our study, the fourteenth year, and especially indicate the necessity to suspect and to take the necessary measures to guard against rickets in sick children."

\*R H Follis, D. Jackson, M. M Eliot, and E A Park Prevalence of rickets in children between two and fourteen years of age, Am J Dis. Child 66 1-11, July 1943.

MEAD'S Oleum Percomorphum With Other Fish-Liver Oils and Viosterol is a potent source of vitamins A and D, which is well taken by older children because it can be given in small dosage or capsule form. This ease of administration favors continued year-round use, including periods of illness.

MEAD'S Oleum Percomorphum furnishes 60,000 vitamin A units and 8,500 vitamin D units per gram. Supplied in 10- and 50-cc bottles and bottles of 50 and 250 capsules. Ethically marketed.

## ANNUAL ORATION

### MEDICINE'S RESPONSIBILITY IN THE PROPAGATION OF POOR PROTOPLASM\*

ALLEN S. JOHNSON, M.D.†

SPRINGFIELD, MASSACHUSETTS

THIS unexpected and undeserved honor has made me acutely aware of my lack of fitness to wear even for this short time the mantle that has graced such distinguished predecessors. Some of them have traced with inimitable charm and grace the progress of medicine through the years. Others have granted to you imaginative glimpses of its achievements in the years to come. As neither endowment nor inclination impels me to assume the role of either historian or prophet I shall ask you to consider with me not where we have been, not where we may be going, but where we are today.

Cynics, idealists, and sentimentalists have tried to define the role of the medical practitioner. I think that most of you who are, like me, average doctors from average communities would agree that our purpose is to enable mankind to make more effective adjustments to the harassments of his environment. Whether these stresses be furnished by trauma, bacteria or psychologic tensions will determine which particular exponent of the healing art is chosen. But the ultimate goal of one and all must be the enhancement of man's capacity for environmental adaptation. Let us examine the balance sheet, then, and evaluate our contributions to man's struggle for existence today.

\* \* \*

Only with profound fear and trembling would one hint that bacterial diseases have been brought under control. Men still die of infection, and undreamed of viral and bacterial mutations may lie in wait for us around the corner. But the contemporary triumphs of modern sanitation and preventive medicine, along with chemotherapy and the more recent antibiotics, certainly warrant more optimism in this field than in some others. In the field of trauma, likewise, these advances, as well

as the contributions of the physiologist, have done much to augment the achievements of the surgeon.

Our accomplishments in the field of endocrinology are still somewhat clouded by the perplexing variety of clinical manifestations and interrelations of these systems. But the vast unexplored vistas that stretch before us should not lessen our appreciation of the concrete contributions to the control of thyroid, parathyroid and pancreatic disease for which we may pay grateful tribute to a singularly gifted group of Boston clinicians. Equally encouraging progress is being made in the field of sex endocrinology, which, unfortunately, is still sometimes obscured by commercial exploitation and premature notoriety.

Thanks to the firm foundation laid by the metabolic investigations of thirty years ago the study of nutrition has progressed from the consideration of the laboratory subject to include not merely the sick patient but also whole groups and nations suffering from dietary deficiency. The smugness of our attitude toward these accomplishments will depend upon whether we are reviving a few individuals suffering from a specific deficiency or whether we are trying to rehabilitate an entire country. We may delegate to our interns the treatment of the individual pellagrin or the alcoholic patient with polyneuritis. But the great bulk of deficiency disease today reflects the economic status of the group rather than the incompetence of their doctors and as such bids fair to be a problem for governmental administration rather than individual therapy alone.

Current propaganda on cancer might suggest to the uncritical that here is a race in which medical accomplishment is being outstripped by some malevolent force. It is true that the male death rate for cancer has shown some increase for each decade from 20 to 75 years over the past 35 years. For example, the Metropolitan Life Insurance Company reports that the cancer death rate for in-

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1948.

†Visiting physician, Springfield Hospital, Springfield.

sured groups from 45 to 75 years of age rose from 1120 per 100,000 in 1911 to 1530 per 100,000 in 1945<sup>1</sup> The cancer death rate for all ages rose from 60 per 100,000 in 1900 to 130 per 100,000 in 1940, but it must be remembered that the age group over 45 years, in which the greatest incidence of cancer occurs, increased 67 per cent<sup>2</sup> during the same 40-year period Furthermore the lay public and the medical profession have grown increasingly cancer conscious during this period, and this fact, coupled with improved diagnostic methods, probably accounts for some of the statistical increase in cancer deaths Fortunately, there is a more hopeful aspect to the problem, which suggests that our intensive efforts are bearing fruit During the period from 1911 to 1945, which showed an increase in male deaths from cancer, there was actually a slight decrease in female cancer deaths And during the past ten years even the male death rate from cancer has begun to level off<sup>1</sup> In this connection it is interesting to examine the cancer mortality trends for the last 12 years, adjusted to the age distribution of the total population and classified according to the site of the origin of the neoplasm Whereas in both sexes there is still an annual increase in deaths from cancer of the respiratory tract, there has been a steady decline in deaths due to cancer of the skin, buccal cavity, stomach and liver Cancer education and improved medical and surgical care have played a large part, but Potter<sup>3</sup> believes that the decrease in deaths from gastric cancer is greater than could be expected from these factors alone The work of the Kennaways<sup>4</sup> suggests that gastric cancer arising after the second 25 years of life may be predestined by factors to which the body was exposed during the first 25 years Potter<sup>3</sup> has pointed out that the change in the death rate from gastric cancer began about 1926, some twenty-five years after significant changes took place in the American dietary,<sup>5</sup> and suggests that there may be a causal relation This raises a new hope of rational prophylaxis, which, with improvements in diagnostic technic and the therapeutic advances implicit in the recent developments of atomic physics, may still further lower the death rate from malignant tumors

Whether or not we appear to be extending man's span of life will depend somewhat on our point of view The pediatrician will point with justifiable pride to the fact that the life expectancy of the newborn white male was 64.44 years in 1945 as compared with 48.23 years in 1900 His sister had an even better outlook by several years At 40 years in 1945 he had thirty years more ahead of him, which was only 3 years more than the 40-year-old male could expect in 1900 But the life expectancy of the 65-year-old man in 1945 was scarcely a year better than that of his father in 1900<sup>6</sup> It appears that the geriatrists can hardly join in the pediatricians' boasting Our control of the infectious

hazards of childhood and early adult life seems to have had little effect on the wearing-out process But whereas the death rate from cardiovascular renal disease has risen from 310 per 100,000 in 1900 to 495 in 1940, an increase of 62 per cent, the proportion of the population over 45 years of age has risen during the same period from 17.8 to 26.5 per cent, an increase of 67 per cent<sup>2</sup> The Metropolitan Life Insurance Company therefore concludes that "The death rate from this group of causes, corrected for the aging of the insured population, dropped virtually 30 per cent (at ages 1 to 74 years) between 1911-1915 and 1940-1944"<sup>7</sup> Although these figures suggest that the current furor about the rising death rate from degenerative vascular disease is misleading, the insignificant increase in expectation of life at 65 years of age today as compared with the figure 45 years ago indicates that immortality is not just around the corner Perhaps this is just as well The catastrophic implications of physical immortality stagger the imagination Already the social and economic dislocations produced by an ever-increasing number of old people in our population is causing concern Imagine the chaos if the aged never died off while even the puny birth rate attributed to college graduates continued<sup>1</sup> Of course even the most enthusiastic geriatrist would blanch at this prospect, but he is inclined to be a little vague when asked to what age it would be socially and individually desirable to extend life expectancy if we had it in our power to do so Perhaps our goal should be the enrichment of living rather than the mere prolongation of life This appears certainly to be more nearly within our grasp, and our contributions in this direction may atone in part for our failure to render man immortal

All this, then, and man's ability to exist at extremes of temperature and barometric pressure bear testimony to medicine's contribution to his physical capacity for environmental adaptation, What of his psychologic adjustments? Has his mental and emotional equipment kept pace with the ever-increasing complexity of his environment? Has science, which has increased the psychologic stresses to which he is subject, helped him to develop behavior patterns of comparable effectiveness? The answer to this question will depend a good deal on what sort of measuring stick we use No one really knows how many maladjusted people there are in his community, though the average practitioner may be inclined to venture a considerably higher estimate at the end of a busy day than at its beginning But even his casual estimates are dependent on the economic status of his clientele and on his own insight Rusk<sup>8</sup> has stated that there are eight million people disabled by mental disease in this country, but the usefulness of this figure depends upon one's definition of disability Selective Service rejections offer a more precise measure

of serious defects in our citizens' mental equipment. During the last eighteen months of the recent war, when the need for dwindling manpower made us progressively less critical of man's frailties, the Selective Service boards rejected 44 per cent of the 5,767,000 examinees, 26.8 per cent of these rejections were for mental disease, 2.6 per cent for mental deficiency, 4.1 per cent for neurologic disorders and 12.8 per cent for subminimal intelligence.<sup>9</sup> In other words, 46.3 per cent of all men rejected were deemed unfit on neuropsychiatric grounds to participate in the struggle for biologic survival. Not all of these were incapable of earning some sort of living or of making some degree of adjustment to their social group. Many were capable of defending themselves individually in a somewhat protective and paternalistic society. But they were deemed incompetent to participate in any such collective defense as was demanded for our survival as individuals and as a nation. In other words, they could not be relied upon to make up a winning team.

Forty-six per cent may seem like a high figure, but Selective Service boards were certainly not being unduly critical when manpower was so urgently needed. They may have been overzealous during the early part of the war, but this is not borne out by figures for medical discharges from the armed forces. During the three-year period of hostilities (1942-1945), 956,232 enlisted men were separated from the Army on certificates of discharge for disability, 379,486 (39.69 per cent) of these were for neuropsychiatric reasons.<sup>10</sup> During the same period the Navy gave medical discharges to 318,798 Navy and Marine Corps personnel, and 104,735 (32.9 per cent) of these were for neuropsychiatric reasons.<sup>11</sup> In other words, in spite of attempts at preliminary screening by Selective Service boards, which eliminated nearly half of those called up, more than a third of these were rejected later, on admittedly neuropsychiatric grounds. These figures probably err, if at all, on the side of conservatism, for all of us who sat on "survey boards" were well aware of the frankly psychiatric character of many of the visceral symptoms that earned for their hosts a nonpsychiatric discharge.

The apologist will suggest that war is abnormal and no fair test of a man's social usefulness, even though it may well test the fitness of a society to survive. What is the incidence of serious maladjustment in civilian life? It would be interesting if we could examine from the psychiatric standpoint all members of a small town as the United States Public Health Service has recently done from the standpoint of diabetes. What would be the incidence of major mental disease and of the less serious types of neuropsychiatric disorders? At present we can form only a rough estimate of the burden that institutionalized nervous and mental disease imposes on society. In the United States in 1946

the hospitals for nervous and mental diseases had 46 per cent of all the hospital beds, and the general hospitals only 43.7 per cent. During the same year the former provided 232,055,685 treatment days, or 51.3 per cent of the daily patient load, compared to 181,232,355 treatment days given by general hospitals.<sup>12</sup> This cannot be attributed to the effects of the war, since the figures for 1936 show that hospitals for nervous and mental diseases provided 192,147,438 treatment days, representing 59 per cent of the daily patient load for all hospitals. Since then general-hospital beds have increased faster than those of the institutions for nervous and mental diseases, but the proportions are still roughly the same. In Massachusetts in 1946 hospitals caring for feeble-minded, epileptic and mentally diseased patients had 50 per cent of the total hospital beds and carried 56 per cent of the daily treatment load of all hospitals in the Commonwealth at a cost of somewhat over \$14,000,000.<sup>13</sup> If we add to the 10,883,205 patient days in these Massachusetts hospitals in 1946 the man days spent in penal institutions, we may have some idea of the magnitude of this problem of maladjustment and the burden on the remaining few of us who have thus far managed to stay out of institutions.

One might conclude that the mental equipment of much of the population has not kept pace in its capacity for appropriate response with the increasing complexity of the environment. We might, for lack of a better scapegoat, blame science for this complexity. Those who have tried to understand a painting by Dali or the writings of Gertrude Stein might feel that the arts, too, must share the blame for this confusion. But these bizarre expressions can be escaped, unlike the noise of machinery, the speed of traffic, the split-second timing of assembly-line technique and the stresses, both social and economic, of a highly competitive society.

Has science attempted to atone for its responsibility by assisting the less well endowed to make more adequate adjustments? Certainly, the acknowledgment of this responsibility is reflected in the growth of psychiatric clinics, special schools for the handicapped, personnel counselors and so forth, but they reach a relatively small proportion of the needy. Much of the expenditure in the field of nervous and mental disease today is allocated to mere custodial institutional care. It is probably true that these misfits are cared for more cheaply, more effectively and with less risk to society than if allowed to run loose. It is open to question whether all these institutions are indoctrinated with the idea of rehabilitation. It is certain that the scanty budgets of many make it almost impossible. As a result many patients are released as soon as they are no longer an obvious menace to themselves or their social contacts although little has been done for long-term rehabilitation. The question may some- ra

whether this protection and perpetuation of poor protoplasm by humanitarian institutions is handicapping society as a whole both economically and genetically. Sooner or later, if present trends continue, society will have to develop methods for enabling this growing horde to effect more adequate social adjustments or else take steps to reduce their appalling fecundity. It is an interesting commentary on our social organization that two antithetical forces like war and humanitarian institutions should protect the unfit at the expense of the fit. Yet we stage a war every twenty-five years and demand that only the physically fit and psychologically well adjusted be allowed the privilege of dying for their country. The unfit are protected to perpetuate the race. The inadequate personality is sustained inside and outside institutions by a variety of federal, state and municipal agencies. Even an indisposition to work seldom results in starvation. The unfit is not wanted by the Selective Service board, and even if he leaks through its wide-meshed screen and withstands the imprecations of his superiors he is seldom assigned to dangerous or fatal duty because he is incompetent and irresponsible. He may be shorn of prestige and material goods, but his voting and procreative powers remain unimpaired and he and his multitudinous

offspring bid fair to be with us always and in ever-increasing numbers. Not all of them can be institutionalized, and not all of them need to be. But they and their problems of adjustment to society constitute a real if unrecognized task to which medicine must shortly apply itself if our contributions to man's psychologic adjustments are to keep pace with our contributions to his physical adaptations.

## CHRONIC THYROIDITIS\*

SAMUEL F. MARSHALL, M.D.,† WILLIAM A. MEISSNER, M.D.,‡ AND DELBERT C. SMITH, M.D.§

BOSTON

CHRONIC thyroiditis, as evidenced by degeneration and fibrotic changes in the thyroid gland, is not a common disease entity but is encountered fairly frequently by the clinician and surgeon experienced in thyroid disease. The recognition of this pathologic process in the thyroid gland is important from the clinical aspect because its firmness, adherence and increase in size of the gland may cause it to be mistaken for malignant neoplasm arising in the thyroid gland.

Classification of this type of thyroid disease has always been more or less troublesome, and loosely used and poorly defined terminology has contributed in no small way to the confusion and disagreement regarding thyroiditis.

More than half a century has passed since Bernhard Riedel,<sup>1</sup> a German surgeon in Jena (1896), presented his original report on the condition of the thyroid gland that has since retained his name and has come to be known as Riedel's struma.

Sixteen years later, Hashimoto<sup>2</sup> reported what he considered to be a distinctly separate clinical and pathologic entity, struma lymphomatosa. Since these original reports, many articles have appeared in the literature concerning chronic thyroiditis, but little has been added to the knowledge of its etiology. Likewise, the clinical and pathologic picture, as known today, has changed little from the original descriptions.

Riedel<sup>1</sup> pointed out in his first report of 2 cases that the gland was of woody hardness and densely adherent to the trachea and surrounding blood vessels and nerves, all of which made it difficult to distinguish from a malignant lesion.

Hashimoto's<sup>2</sup> original report consisted of 4 cases, all in women over forty years of age, who presented essentially the clinical picture as it is known today. He was aware of the absence of inflammatory reaction and the lack of adherence to surrounding structures. He went further to point out the post-operative picture of myxedema, which disappeared after the internal administration of thyroid substance. The chief pathologic findings described were diffuse lymphocytic infiltration, atrophy of

\*Presented at the annual meeting of the New England Surgical Society Providence, Rhode Island October 3, 1947.

†Surgeon, Lahey Clinic, surgeon, New England Deaconess and New England Baptist hospitals.

‡Member, Department of Pathology, New England Deaconess Hospital.

§Fellow in surgery, Lahey Clinic.

the acinar epithelium, with absence of colloid, and proliferation of connective tissue

Despite the clarity with which these authors described two distinctly separate clinical entities, much confusion has occurred. This has been the result of the many variants in the microscopical picture as well as in the clinical findings. The purpose of this paper is not to give a historical review of the numerous controversies existing over the years or of the literature, but to present a summary of a pathological and clinical study of a group of cases encountered in which operation was performed at the Lahey Clinic during the period of 1928 to 1946, inclusive. As every surgeon knows, these cases may present some perplexing problems in technique at the operating table. The present study was undertaken with the hope that certain conclusions could be reached from the observation of a fairly large series of cases that would be of value in the diagnosis and further management of these patients.

During the eighteen-year period under consideration 187 cases of undoubted chronic thyroiditis were encountered in the pathological examination of the specimens from approximately 25,000 patients requiring thyroidectomy. There were many other cases in which a tentative diagnosis of thyroiditis was made on the excised tissue, but since a careful pathological review and reclassification of these specimens revealed them to be lacking in many of the characteristics thought necessary to establish this diagnosis, they were discarded in the study of this material. Also, no cases of thyroiditis occurring in hyperplastic goiter, adenomatous goiter or thyroid tumor are included, although the condition may complicate such already diseased glands. It is evident that this condition is by no means rare, since this represents an incidence of 0.75 per cent. These 187 cases, selected after careful correlation of the clinical findings with the microscopical picture, form the basis of our report.

Many other cases were found in which a clinical diagnosis of thyroiditis was made, but these patients were not submitted to operation, so that pathological examination could not confirm the accuracy of this diagnosis and, of course, they cannot be included in this study. There can be no doubt that with sufficient experience in the disease a fairly large number of cases can be recognized clinically and that, in the event of no complications, operation can safely be avoided. Because of enlargement of the thyroid gland, development of pressure symptoms, constriction of the trachea or inability definitely to exclude cancer, however, a certain number of patients must submit to operation either to decompress the trachea or to rule out malignant degeneration. Some of these patients came to surgery with enlarged thyroid glands that were mistakenly construed by the clinician to be adenomatous goiter. A correct preoperative diag-

nosis of thyroiditis in the group of 187 cases was made in only 44 patients, or 23.5 per cent, so that the preoperative error in diagnosis of patients submitted to operation is considerable. It is also well to emphasize the fact that the uncertainty regarding the type of thyroid disease present necessitates biopsy or resection of the thyroid gland, and this very fact accounts for the low percentage of correct preoperative diagnosis in this group of operated cases. In many cases the pathologist has difficulty diagnosing the condition correctly without microscopical study. Dr. Frank H. Lahey has often described the characteristics that enable thyroiditis to be recognized clinically in a large number of cases, but the necessity for repeated periodic examinations has also been constantly emphasized. Operation is demanded when even the slightest suspicion of a malignant lesion exists, and progressive enlargement or constrictive symptoms occurring in a previously clinically recognized thyroiditis may also require surgical interference at some time after the initial diagnosis has been established.

#### PATHOLOGY

Concerning the pathology of the various forms of thyroiditis it should be pointed out that there are apparently several ways in which the gland may react to injury or irritation. These basic types of reaction are seen whether the injury is the result of actual infection, trauma, vascular disturbances or altered physiology. Either the stroma or the epithelium of the thyroid gland may show considerable change in response to irritation or injury. The stromal changes consist of fibrosis and infiltration with inflammatory cells, of either mononuclear or polymorphonuclear type. The epithelial changes consist of diminution in the size or atrophy of the acini, acidophilia of the thyroid cells to become the Hürthle type and occasionally epidermidization of the epithelium. At times colloid is allowed to spill out of the follicle into the stroma, since colloid is an irritant, it causes an inflammatory response, with a foreign-body, giant-cell reaction, when it is free in the stroma.

Examples of such changes are seen in the pathologic states of hyperplasia, adenomatous goiter and tumor. In hyperplasia there is frequently an infiltration with lymphocytes and often the formation of secondary lymph follicles. A small amount of fibrosis often accompanies the lymphoid infiltration particularly in the later stages of involution. The so-called "exhaustion atrophy" of the thyroid gland is a state that presumably follows overactivity, and in this condition there is not only infiltration with lymphocytes and some fibrosis but also frequently an acidophilia of the epithelium.

In adenomatous goiter, fibrosis of the gland owing to hemorrhage or colloid spillage is frequent. Not uncommonly lymphoid infiltration and compression of the acini adjacent to the capsule of the

tumor are found in adenomas. In malignant tumors there is, of course, the inflammatory exudate frequent in cancers.

At times the thyroid gland is the site of similar basic inflammatory changes, which apparently are not associated with hyperplasia, adenomatous goiter or tumor. It is this group, called chronic thyroiditis, with which the present study is involved, cases

FIGURE 1 Infection of the Thyroid Gland in the Subacute Stage in a Forty-Six-Year-Old Man Who Complained of Pain and Swelling in the Thyroid Region of Five Weeks' Duration. Note the numerous polymorphonuclear neutrophils in the stroma and in the large acinus at the lower right. Fibrosis and foreign-body giant cells (hematoxylin and eosin,  $\times 50$ ).

that showed a definitive type of pathologic change in addition to inflammation were not included.

Excellent discussions and reviews of the pathology of chronic thyroiditis can be found in detail in the papers of Womack,<sup>3</sup> McClintock and Wright,<sup>4</sup> Joll<sup>5</sup> and others,<sup>6, 7</sup> and a lengthy description is unnecessary here. For the purposes of clinical comparison, it was found that cases of chronic thyroiditis could easily be segregated into three main groups, which were reasonably distinct both pathologically and clinically. The great majority of cases fall fairly easily into one of the three categories. The more important characteristics of each group are described below.

#### Group I

This group consisted of 41 cases showing a reaction that seemed to be due obviously to infec-

tion. It is well known that acute infections of the thyroid gland occur, but since such a gland is not removed surgically in the acute stage of an infection, no acute infections were present in this series. A group of 18 glands, however, showed changes that may be called subacute inflammation (Fig 1), there was a moderate degree of fibrosis with numerous inflammatory cells, chiefly polymorphonuclear neutrophils often centered in acini. Such acini usually showed degeneration and spillage of colloid with foreign-body, giant-cell response, although the latter cells were not numerous in this stage. In the chronic stage of the infection represented by 18 other specimens (Fig 2), the polymorphonuclear leukocytes had largely or completely disappeared, but numerous foreign-body giant cells were still present reacting to colloid. Also scattered throughout the fibrotic stroma were numerous lymphocytes and plasma cells. The fibrotic stage of the infection apparently represents the healed stage

FIGURE 2 Infection of the Thyroid Gland in the Chronic Stage in a Thirty-Seven-Year-Old Woman Who Had Soreness and Enlargement in the Neck for Four Weeks and a Tonsillectomy for Chronic Tonsillitis One Year Previously. Note the numerous foreign-body giant cells (hematoxylin and eosin,  $\times 50$ ).

(Fig 3), and in this terminal phase foreign-body giant cells were usually absent and other inflammatory cells few in number—it is this stage that usually has been designated as Riedel's struma. In none of the stages in this group was the epithelial change characteristic, and although considerable epithelium was apparently destroyed and replaced by the infection and subsequent fibrosis, that which remained usually showed little or no change

and no evident atrophy. Acidophilia was absent or slight, there was occasional epidermidization. Grossly, the glands in this group were all firm, fibrous and often gray or white. The capsules in most specimens were adherent both to the thyroid gland and presumably to the adjacent structures, since they were infiltrated microscopically with the inflammatory process. The change in the gland was sometimes focal, but often diffuse.

### Group II

The second group was composed of 78 thyroid glands, which were generally designated as Hashimoto's struma or struma lymphomatosa. This group pathologically showed a marked infiltration of the stroma with lymphoid cells and the formation of numerous secondary lymph follicles (Fig 4). The lymphoid infiltration in these glands was often little more than that seen in many cases of primary

fibrosis, in small strands and cords, the fibrosis was in broader bands only when pronounced, as in the first group. Grossly the specimens in this category averaged about 100 gm in weight for the two lobes (Fig 5). They had a rubbery consistence.

FIGURE 3 Infection of the Thyroid Gland, Largely Healed, in a Fifty-Two-Year Old Woman Who Had Swelling in the Neck with Difficulty in Breathing for Four Years and with Restricted Breathing on Raising the Arms While Combing Hair. Note the marked fibrosis. Many of the remaining acini are little changed (hematoxylin and eosin  $\times 50$ ).

hyperthyroidism, and such a marked lymphoid infiltrate is not sufficient evidence in itself to warrant placing the gland in this general group. The specimens, in addition to the lymphoid infiltration, uniformly showed atrophy and marked acidophilia of the epithelium. Occasionally there was some degeneration of colloid with foreign body giant-cell reaction, but this was inconstant. Although the stroma always showed at least a small amount of

FIGURE 4 Struma Lymphomatosa in a Forty-Six-Year Old Woman Who Had Had Cough for Three Years Increasing in Size for the Past Year, with Occasional Coughing and Choking Spells and with Difficulty in Breathing on Exertion. Note the characteristic marked lymphoid infiltration and atrophy of epithelium (hematoxylin and eosin  $\times 50$ ).

The change was diffuse and homogeneous throughout both lobes. The capsules were grossly preserved with no suggestion of adherence.

### Group III

This was a conglomerate group and undoubtedly included thyroiditis resulting from several causes. The specimens showed little that was characteristic grossly. Microscopically, they showed the basic stromal (slight fibrosis and round-cell infiltration and occasionally spilled colloid) and epithelial (absent or mild acidophilia and atrophy) changes common to all injuries of the thyroid gland, but the changes were of such a mild degree that a further classification was not possible. It seemed best to designate this group of 68 cases as simply "chronic thyroiditis, nonspecific." Two cases of thyroiditis presumably due to irradiation and 1 case of probable syphilis of the thyroid gland were not included. There were no examples of tuberculosis of the gland.

Some of the thyroid glands in this group appeared similar to the "exhaustion atrophy" state, although a history of previous hyperthyroidism was unusual. Other glands suggested that the inflammatory response was the result of a mild infection, which was not severe enough to warrant inclusion in Group I. Still other specimens must have represented an early stage of struma lymphomatosa, but with changes too mild to be pathognomonic. Vascular changes were considered a possibility as

rather indefinite mild inflammatory changes, which must be designated as nonspecific chronic thyroiditis.

### SYMPTOMS

The outstanding symptoms presented by patients with chronic thyroiditis in this series were more or less similar in all three groups of cases. The most common complaint was that of goiter or enlargement of the neck (Table 1), and was the initial complaint of 80 per cent of the patients. Local manifestations of thyroid disease were pressure symptoms, breathing difficulties, choking sensation and difficulty in swallowing in a much smaller percentage, and were present in the majority of the more advanced or more chronic cases. Neck discomfort was outstanding in the cases of infection thyroiditis (Group I), occurring in 1 in 4, and this is to be expected in view of the marked tendency to fibrosis and constriction in this type of thyroiditis. Alteration of the general physical condition, which was not a prominent feature unless myxedema was present and which occurred infrequently in the form of nervousness or fatigue, was observed more often in patients with a strong tendency to neurosis or phobia of cancer. The average duration of symptoms in all groups was approximately two years.

Diagnosis is established by the presence of an increase in size of the thyroid gland. It may be

FIGURE 5 *Struma Lymphomatosa* in a Sixty-One-Year-Old Woman Who Complained of Marked Swelling in the Neck of One Year's Duration

Note the lobulation and the thin capsule

an etiologic factor in this group, but no changes could be found that could be directly attributed to vascular lesions. Still another etiologic possibility is trauma.

It is possible, then, to divide chronic thyroiditis into three groups pathologically. Group I includes cases of thyroiditis in the true sense—that is, inflammation of the thyroid gland caused by actual infection. The terminal or healed stage of this type of thyroiditis has been known as Riedel's struma, but it seems more logical to include all stages of infection of the thyroid gland under one grouping no matter whether the infection is acute, subacute, chronic or healed. Group II, composed of specimens that have previously been designated as struma lymphomatosa, appears to be distinct and separate from thyroiditis caused by infection. The pathological changes are characteristic enough in most cases to warrant a separation of these specimens from the other types of thyroiditis, although the etiology is unknown. In addition to these two groups, which present more or less specific pictures pathologically, there is the third group of

TABLE 1 *Presenting Symptoms in Cases of Chronic Thyroiditis*

SYMPTOM	GROUP I NO. OF CASES	GROUP II NO. OF CASES	GROUP III NO. OF CASES

fairly large (two to four times the size of the normal gland) and firm, and this feature is characteristic of all three groups. The enlargement is bilateral in the majority of cases (occasionally it is unilateral in Riedel's struma) and is symmetrical. The anatomic outline of the lobes is maintained, as is the sharp apex of the upper pole where the superior thyroid vessels enter. The firmness of the gland in Riedel's thyroiditis may be very marked, it is woody or stony hard, with a tendency to adherence to the trachea and surrounding structures, and gives to the examiner a sensation of immobility. The induration of struma lymphomatosa is more elastic and resilient but still quite firm, it is not accompanied by the adherence to surrounding structures noted in the first group. The differentiation from

cancer in the majority of cases of all groups can be made readily, but it is well to point out that cancer cannot definitely be ruled out in a small percentage of cases, and these patients must submit to surgical interference consisting of either biopsy or partial resection of the gland. Thyroiditis usually arises in a presumably normal gland, which has not previously been the seat of a goiter, and no

marked lymphoid infiltration with little or no secretive epithelium of Hashimoto's struma represents the healed or end stage of the process in these two groups. There is no evidence that in the chronic stage of thyroiditis acute inflammatory changes will develop. Fever does not accompany the process of chronic thyroiditis, and signs of inflammation such as redness and marked tenderness

history of nodular goiter can be obtained. Carcinoma arises commonly on the basis of an adenoma, and consequently the gland is usually nodular from the beginning. As the malignant growth involves and breaks through the capsule, the gland loses its anatomic outline and symmetry, and ordinarily the neoplasm involves one lobe or the isthmus and the fixation is local over the tumor and does not possess the symmetrical fixation of Riedel's thyroiditis. If the clinical diagnosis of thyroiditis can be reasonably assured or if a biopsy specimen

in the neck are not described nor have we been able to obtain the history of such local inflammation in any of the cases in this group. Spontaneous regression of the inflammatory process probably also does not occur.

#### SEX DISTRIBUTION

It is well known that the thyroiditis described by Hashimoto is rarely seen in men, and in the group of 78 cases, only 1 occurred in a male patient (1 male to 77 females), whereas infectious thyroiditis

is obtained to establish the absence of neoplasm, there is no evidence that the malignant degeneration is likely to develop in a gland involved with thyroiditis. The various stages of degenerative and fibrotic changes noted on pathological study in Groups I and II may well indicate that the disease is progressive in character and that the advanced sclerotic, woody gland of Riedel and the

(Group I) may occur in either the male or the female (Tables 2 and 3). About half the cases in the literature are said to have occurred in men, in our series there were 11 males to 30 female patients. In the cases of nonspecific thyroiditis (Group III) there were 3 males and 65 female patients (Table 4). We have no data to indicate whether the sex distribution in these cases was significant, but since thyroid

disease is more common in women, the tendency of greater incidence in female patients may not be especially helpful in diagnosis of thyroiditis and may not be especially significant. In view of the infrequency of Hashimoto's thyroiditis in men, however, it is extremely unlikely that a preoperative

but these patients should be observed at stated intervals for evidence of compression of the trachea and to exclude the possibility of overlooking malignant tumors. If treatment is indicated in any case, we believe that operation offers the best method. It should consist of either partial resection of the

AGE

The average ages for the three groups of cases were essentially similar and were not especially significant. Thyroiditis of the infectious type or of

gland or excision of the isthmus to relieve constriction of the trachea. We have not treated any of these patients with irradiation although there are some reports of good results in the literature. We believe that additional fibrosis produced by the reaction of irradiation may well increase the constriction on the trachea and also further destroy remaining thyroid-secreting epithelium. The principal indications for surgery are definite pathologic evidence that the process is not malignant and relief of pressure symptoms or release of tracheal constriction. In most cases of Riedel's thyroiditis the diagnosis can be established at the operating

FIGURE 6 Stage in Operation for Chronic Thyroiditis. The isthmus and medial portions of both lobes have been removed to clear the anterior part of the trachea of all thyroid tissue. The sternohyoid muscles have been sutured to the trachea to prevent adherence of the lateral lobes and recurrence of compression.

FIGURE 7 Narrowing of the Trachea Caused by Compression from Chronic Thyroiditis (Reprinted from Lahey<sup>8</sup> by Permission of the Publishers)

the Hashimoto type is rarely seen before the age of thirty-five, but may occur at any age thereafter (Table 2)

TREATMENT

We have already called attention to the fact that diagnosis can be made in a large number of cases and that treatment in many cases is unnecessary,

table by the appearance of the thyroid gland upon exposure and by its adherence to surrounding structures, and biopsy can immediately confirm this. Radical resection is unnecessary, and may be difficult because of the stony hardness of the gland and the difficulty in dissection and exposure of the normal structures such as the recurrent laryngeal

nerves and parathyroid glands. If radical removal is persisted in when marked induration and adherence are present, serious complications may result from injury to the parathyroid glands and to the recurrent laryngeal nerves. Furthermore, release of pressure on the trachea can be obtained by simple removal of the thyroid isthmus, as proposed by Lahey,<sup>8</sup> which separates the lobes and releases the vise-like pressure on the trachea. Suture of the prethyroid muscles to the tracheal fascia prevents the lobes from becoming adherent to each other with return of pressure on the trachea (Fig. 6). Inasmuch as active thyroid-secreting epithelium is still present in the sclerosed gland in Riedel's thyroiditis, extensive partial removal is undesirable, since this procedure decreases thyroxin secretion still more and increases the number of cases in which myxedema develops.

Bilateral partial thyroidectomy is advisable in Hashimoto's struma and should be radical enough to relieve the compression (Fig. 7) noted in these cases as well as to improve the cosmetic effect by removal of an enlarged gland. Large remnants of either lobe should be allowed to remain to avoid injury to the recurrent laryngeal nerves or parathyroid glands, although the lack of adherence of the gland precludes much risk. It is evident that a radical resection in these cases will result in earlier signs of myxedema, but many of these patients exhibit hypothyroidism before operation, practically all patients (7 per cent preoperatively and 27 per cent postoperatively in Group I, 8 per cent preoperatively and 79 per cent postoperatively in Group II and 6 per cent preoperatively and 50 per cent postoperatively in Group III) develop myxedema later regardless of how much thyroid tissue is removed. It matters only that sufficient tissue be removed to relieve pressure symptoms and constriction of the trachea, we believe that this can be done best by a liberal partial thyroidectomy.

#### TYPE OF OPERATION

From this discussion, excision of the thyroid isthmus is considered sufficient in most cases of infection thyroiditis, and a partial bilateral thyroidectomy is desirable in struma lymphomatosa. The best procedure in patients in Group III is excision of the isthmus, but this may have to be modified if sufficient relief of pressure cannot be obtained by such a conservative procedure. In these cases, as in Group I, every effort should be made to conserve thyroid tissue to avoid myxedema. The frequency of myxedema in the various groups after the various operative methods may well serve as a guide in planning treatment in these cases.

Thyroid deficiency is present or develops after operation in many cases. It is much less common

in the infectious type (27 per cent), but in the more advanced stage of this group (Riedel) it was noted in 57 per cent. As stated above, patients with Hashimoto's struma developed signs of thyroid deficiency in 79 per cent of the whole group, but this incidence was increased only 8 per cent if partial thyroidectomy was done. In the nonspecific group, thyroid deficiency was noted in 50 per cent of cases, but a decreased tendency (33 per cent) was noted with resection of the isthmus only. In some instances too few cases were observed to draw final and definite conclusions, but our studies seem to point to the value of conserving thyroid tissue whenever possible, except possibly in the Hashimoto type.

Postoperative complications consisted of tetany and recurrent-laryngeal-nerve paralysis (Tables 2, 3 and 4), 2 patients required temporary tracheotomy after operation for Hashimoto's struma, but this was necessary because of edema arising after operation in myxedematous patients, which is not an uncommon complication and did not follow nerve injury. In view of the possible tendency for patients with myxedema to develop postoperative edema it is wise to correct any thyroid deficiency by oral administration of desiccated thyroid before operation and thus to avoid respiratory difficulty after operation. We believe that with recognition of the necessity for exposure of the recurrent nerves in all partial resections of the thyroid gland for any cause, the complication of recurrent-laryngeal-nerve paralysis can be avoided or at least seldom encountered.

#### SUMMARY

A report of 187 cases of chronic thyroiditis is presented, and an attempt is made to analyze the clinical and pathological characteristics.

Chronic thyroiditis occurred not infrequently in our experiences with approximately 25,000 operations for thyroid disease, an incidence of 0.75 per cent.

An attempt is made to classify these cases into three groups on the basis of pathological changes noted in the excised gland and to correlate these findings with the clinical course of the patients.

Clinical diagnosis of chronic thyroiditis is possible, and it is clinically possible to distinguish thyroiditis from thyroid cancer in a large number of cases.

Treatment is unnecessary in many cases but when necessary to establish diagnosis or to relieve pressure on the trachea, surgical removal of the isthmus or partial thyroidectomy offers the best method.

Myxedema develops with the course of the disease, and operation should be planned to minimize this tendency as much as possible.

Operative complications can be avoided or decreased with a better selection of the type of opera-

tion in each case and with improvement in technic of thyroid resection

## TUMORS OF SALIVARY-GLAND ORIGIN\*

GRANTLEY W. TAYLOR, M.D.,† AND GERALD G. GARCELON, M.D.‡

BOSTON

THIS report summarizes the experience with tumors of salivary-gland origin observed at the Massachusetts General Hospital from 1930 to 1941, inclusive, and at the Pondville State Cancer Hospital from 1927 to 1941, inclusive. Table 1 presents the distribution of the cases.

The relative frequency of carcinoma and mixed tumors of the parotid and submaxillary salivary

marily with the mixed tumors and carcinomas of the parotid and submaxillary salivary glands. Identical tumors may occur in abnormal locations about the mouth and elsewhere, principally in the cheeks, palate or lips. Their management is the same as that of the corresponding tumors of the salivary glands.

### DIAGNOSIS

The usual patient presents a symptomless tumor in the submaxillary or parotid region, discovered accidentally or because some fullness or swelling is noted. The differentiation between mixed tumor and carcinoma on the basis of history and physical findings alone is difficult and often impossible. Although the relation of mixed tumor to carcinoma is obscure, the diagnosis of carcinoma arising from mixed tumor was made on pathological study in 10 cases in the present series (16 per cent of the cases of carcinoma). In certain other cases of long duration the pre-existence of a benign tumor may be assumed. Analysis of the preoperative duration disclosed that more than half the mixed tumors were known to be present for over three years, in contrast to the carcinoma cases, in which nearly half the patients gave a history of known duration of a year or less. The mixed tumors are generally characterized as sharply defined, firm rather than hard, and movable. In contrast, the carcinomas are often less sharply defined, are usually described as hard rather than firm and are already fixed in the great majority of cases when the patient is first seen. Whereas both tumors may occur at any age, from the second to the ninth decade, the greatest concentration of mixed tumors takes place in the third and fourth decades, and the carcinomas occur principally in the sixth and seventh. Primary facial-nerve palsy was observed in 15 cases of carcinoma of the parotid gland (25 per cent), but it did not occur in the cases of mixed tumor, although in 1 case there was some twitching of the lip suggesting nerve irritation. Cervical-lymph-node enlargement was noted

TABLE 1 Tumors of Salivary-Gland Origin

TYPE OF TUMOR	PAROTID GLAND NO OF CASES	SUBMAXILLARY GLAND NO OF CASES	ABNORMAL LOCATIONS NO OF CASES
Mixed	115	16	12
Carcinoma	61	12	2
Miscellaneous	17	6	

glands is unusually high in this series of cases as shown in Table 1. This is due to the fact that more carcinomas than mixed tumors of the parotid and submaxillary salivary glands were observed at the Pondville State Cancer Hospital during the period studied. A truer incidence of the relative frequency of these tumors is shown in the Massachusetts General Hospital cases, in which there were 91 mixed tumors and 25 carcinomas of the parotid gland and 14 mixed tumors and 8 carcinomas of the submaxillary salivary gland.

The miscellaneous group comprises cysts, adenomas, sarcoma, Mikulicz's disease and various other conditions. These tumors cause confusion in diagnosis. They are sufficiently rare so that decision regarding treatment must be made on the merits of the individual case. Our present concern is pri-

in association with 4 cases of mixed tumor of the parotid gland. Established cervical-lymph-node metastases were present in 29 cases (47 per cent) of the parotid carcinomas. Finally, the possibility of remote metastasis should be considered in cases of carcinoma. Pulmonary metastases were discovered in 4 cases of parotid carcinoma primarily, and remote disease in the lungs, skeleton, liver and other areas was observed in 12 more during the later course of the disease. These clinical con-

and an additional patient suffered facial-nerve injury. Among 15 primary and 10 recurrent cases treated by the Adson-Ott operation described above there were no recurrences or facial palsies in the primary cases, whereas there were 3 recurrences and 1 facial palsy in the recurrent cases.

The relatively large number of patients who first present themselves at the clinics with recurrence following operation elsewhere suggests that enucleation of the tumors is rather widely followed, and

TABLE 2 Clinical Data in Cases of Mixed Tumors and Carcinoma

TYPE OF TUMOR	MEDIAN AGE OF PATIENTS	MEDIAN DURATION OF TUMOR	TUMOR OF HARD CONSISTENCE	MOVABLE TUMOR	ENLARGEMENT OF CERVICAL LYMPH-NODES	PRIMARY FACIAL NERVE PALSY	REMOTE METASTASES
	%	%	%	%	%	%	%
Mixed	30-40	More than 3	30	30	3	25	25
Carcinoma	50-60	Less than 3	70	15	47	75	75

trasts between mixed tumors and carcinomas are summarized in Table 2.

It is evident from these data that in many cases the diagnosis on clinical evidence is ambiguous and that exploration must be resorted to. At the time of operation the discovery of lack of definition of the limits of the tumor, the persistence of fixation as the operation progresses and the apparent implication of the branches of the facial nerve in the tumor itself all argue for the probable diagnosis of cancer. In cases of doubt, it is necessary to resort to immediate pathological examination.

### TREATMENT

#### Mixed Tumors

In recent years there has been increasing recognition that simple enucleation of mixed tumors invites the possibility of recurrence and that simple enucleation of a tumor that proves to be carcinoma destroys the best chance of effecting a cure. The present practice is essentially that described by Adson and Ott,<sup>1</sup> in which the facial nerve is identified and exposed, and the part of the gland lying superficial to the nerve, including the tumor, is completely removed. In the cases in which the mixed tumor originates in the part of the gland lying on the deep medial aspect of the nerve, the nerve and its branches may be lifted to permit removal of the tumor-bearing area.

There were 94 primary cases of mixed tumor of the parotid gland and 21 cases with recurrent tumors after primary treatment elsewhere. Eighty-five patients with primary cases were treated by surgery, of whom 8 developed recurrences and 6 had some facial-nerve injury. Of 19 patients with recurrent tumors submitted to operation, 3 had already suffered injury to the facial nerve. Four secondary cases developed later recurrence,

that it is associated with considerable risk of recurrence and facial-nerve injury. Our own experience with simple excision or enucleation (61 cases with 5 recurrences and 3 cases of facial palsy) confirms the unsoundness of this method of management. Although some patients were treated with incomplete excision supplemented with radiation, we had no significant success with this method. However, our experience is too limited to permit evaluation of the various proposed technics of radiation as supplementary or definitive therapy for mixed tumors.

Several years ago McFarland<sup>2</sup> suggested that mixed tumors may become increasingly benign with time and growth, and that recurrence is less likely to follow operation on large tumors of long duration than operation on small tumors. Analysis of the present group in respect to size of the tumor in relation to the incidence of recurrence does not support McFarland's contention. In fact, the highest incidence of local recurrence was associated with the largest primary tumors.

There were 8 recurrences among the primary cases subjected to operation (10 per cent). All these followed operative technics that have since been discarded. All patients were submitted to a second operation, which was successful in all but 1 case, in which a third operation was necessary to effect a cure. Among the patients with secondary cases subjected to operation, there were 4 (20 per cent) in whom a recurrence took place after operation, requiring a third operation for control.

It seems unnecessary to labor the point that local recurrence is due to improper surgical technic. There was a definite notation that the tumor was encapsulated in 83 cases, and in 23 of these the tumor capsule was broken or cut into. Follow-up observation on 16 of these patients disclosed recurrence in 4 (25 per cent). There is considerable likelihood that

the incidence of recurrence is greater than these figures indicate, because a long time may elapse before the recurrence is manifested. In nearly half our cases, the recurrence took place after five years.

The mixed tumors of the submaxillary salivary gland are treated in the same way as those of the parotid gland — namely, by radical removal of the gland. Recurrence took place in only 1 case in our series, in which only a small part of the gland had been removed along with the tumor.

### Carcinomas

The treatment of carcinoma of the parotid gland depends upon the stage of the disease. In the earliest stage, the tumor is first recognized as carcinoma by the pathologist. Provided that a wide excision of the Adson-Ott type has been employed, there does not appear to be any indication for further operation at the moment. Many such cases are given a course of postoperative x-ray therapy, but review of the material does not suggest that recurrence is avoided or delayed as a result. Careful follow-up observation over a long period will detect cases that develop cervical-lymph-node metastases requiring neck dissection or that present operable local recurrence in the parotid region.

The second stage includes cases in which the diagnosis of carcinoma is made preoperatively or during the course of the operation. These cases call for radical measures at once, with sacrifice of the nerve if it is possibly implicated and with radical neck dissection. Finally, a large number of cases are inoperable when the patients are first seen, owing to wide local fixation, inoperable metastases or remote dissemination. These patients are treated with various operations or combinations of surgery and radiation, depending upon the problem presented by the individual case. The carcinomas are not particularly sensitive to radiation therapy.

The secondary cases in this series fall into two groups, those with recurrence following operation elsewhere, and a smaller group of patients who are sent for prophylactic postoperative radiation. Those with established recurrences are treated essentially like the primary cases of corresponding stage.

Among the 61 cases of carcinoma of the parotid gland, 40 were primary cases, and 21 had received treatment elsewhere. Radical removal of the parotid tumor with or without supplementary radiation, was employed in 33 cases, in which 5 patients were cured, 7 were untraced and the remainder were failures. Radical neck dissection was added to removal of the primary tumor in 7 addi-

tional cases, but there were no cures in this group. Seventeen primary cases were treated with radiation alone, with no cures. It is evident that the results of treatment are unsatisfactory and that the principal difficulty is due to the advanced stage of the disease when the patients are first seen. Analysis of the causes of failure indicates that recurrence in the operative field was the principal one, taking place in 19 cases.

There were 12 patients with carcinoma of the submaxillary salivary gland. Ten of these were subjected to surgical treatment, with or without supplementary radiation. There were no cures in this group. Here again there was failure to control the primary disease, rather than metastases. When it is realized that a large percentage of submaxillary-gland tumors are carcinomatous (Table 1), the desirability of more radical local interventions is obvious.

There were 2 carcinomas of salivary-gland origin in abnormal locations, 1 involving the palate and the other the antrum. The former case was treated by electrosurgical excision and electrocoagulation, and the other by multiple operations followed by radium and x-ray radiation. Both patients died because of failure to control the disease locally.

### SUMMARY

The experience of the Massachusetts General and Pondville hospitals with tumors of salivary-gland origin is reviewed.

The differential diagnosis of mixed tumors and carcinomas is difficult, but certain characteristics permit a presumptive diagnosis.

The treatment of mixed tumors is satisfactory provided that a wide resection of the gland is carried out. Visualization of the facial nerve is the best safeguard against injury. Enucleation of the tumor invites recurrence.

The treatment of carcinoma is unsatisfactory. Failure to establish the diagnosis in early cases results in the employment of subradical procedures and invites recurrence. A large percentage of the patients present advanced and incurable disease when they are first seen. Early wide resection of the gland offers the best chance for cure. In our experience radiation treatment is not effective.

## CLINICAL NOTE

## THE USE OF PARA-AMINO BENZOIC ACID IN A CASE OF ROCKY MOUNTAIN SPOTTED FEVER

JOHN O NILES, M.D.,\* AND  
GEORGE C BOURNE, M.D.†

HYANNIS, MASSACHUSETTS

PARA-AMINO BENZOIC acid was first reported in the treatment of louse-borne rickettsial diseases in 1942 by Snyder and his associates.<sup>1</sup> After experimental work on the Rickettsia of Rocky Mountain spotted fever by Hamilton, Plotz and Smadel<sup>2</sup> among others, its subsequent use in the treatment of human beings was reported by Rose et al.<sup>3</sup> and other investigators. The patient in the following case was treated according to a schedule reported by Greeley.<sup>4</sup>

## CASE REPORT

A 4½-year-old girl was admitted to the hospital on June 4, 1947, with a history of fever and rash over the upper and lower extremities of 2 days duration. One week prior to entry wood ticks had been removed by the mother from the child's head. Two days before admission a lump was noted on the back of the child's head. She complained of nausea and abdominal discomfort and vomited on two occasions on the day prior to admission and the temperature was 104 F. The child also complained of a headache and chilly sensations. She appeared to be drowsy, restless and irritable when seen by Dr. Carroll Keene of Chatham, Massachusetts, who advised hospital admission because of a rash suggestive of spotted fever.

The past history was irrelevant; there had been no recent exposure to childhood diseases.

The family history was noncontributory.

Physical examination revealed a well developed and well nourished child, complaining of headache and chills who was somewhat irritable and delirious. The head was normal except for nontender cervical lymph nodes in the posterior triangle on the right side. There was no evidence of infection in the scalp or localized areas of hematoma. The eyes and ears were normal. The nose and throat were not remarkable except for a slight, nonpurulent, nasal discharge. The lungs were normal to auscultation and percussion. The heart was normal in size, shape and rhythm. Examination of the abdomen was negative. There were no masses or areas of tenderness. The liver and spleen were not palpable. The extremities were normal. Neurologic examination was essentially negative except for some general hyperactivity. The skin showed a finely macular discrete rash scattered over the upper and lower extremities. It was located mainly below the elbows and knees becoming more pronounced toward the periphery and was present on the palms of the hands and the soles of the feet. The macules blanch on pressure and occasional petechiae were also noted. Scattered macules were observed on the chest and neck, and a few on the back and abdomen. None were seen on the face.

The temperature was 102.8 F; the pulse 100 and the respirations 22. The blood pressure was 90/40.

Examination of the blood revealed a red-cell count of 4,500,000, with a hemoglobin of 14.5 gm per 100 cc., and a white-cell count of 9000, with 68 per cent neutrophils and 32 per cent lymphocytes. Urinalysis showed a specific gravity of 1.032 and negative tests for albumin and sugar with occasional white cells noted in the sediment. The nonprotein nitrogen was 32 mg., and the blood sugar 140 mg. per 100 cc. The sedimentation rate was 20 mm. in 1 hour (Westergren method). Blood was drawn for agglutination tests for typhoid fever, undulant fever and Weil-Felix reactions. The results are reported below.

The patient was treated symptomatically with fluids and aspirin on admission. Approximately 17 hours after entry, the child was given 5 gm of para aminobenzoic acid in 25 cc. of a 5 per cent sodium bicarbonate solution. 60 cc of pineapple juice was used to disguise the acid taste of the solution. This, however, was vomited soon after ingestion. The same dosage and preparation were repeated in 2 hours, and this was also vomited. Approximately 21 hours after admission 2 gm of para aminobenzoic acid in 10 cc of 5 per cent sodium bicarbonate solution was given in 60 cc of grape juice. This was retained and continued to be retained throughout the administration of this medication at 2 hour intervals and at the same dosage for the following 6 days. Additional treatment consisted of a high protein, high-calorie diet fluids as tolerated and a preparation high in vitamin content three times a day with vitamin K injections every other day. Daily white-cell count and differential counts were done as well as daily urinalysis. Approximately 24 hours after the first successful administration of the para aminobenzoic acid the temperature had fallen to 99°F. The pulse which had varied between 120 and 160 fell to 100. Within 48 hours after the administration of para aminobenzoic acid the temperature was normal and remained so throughout the patient's stay in the hospital. The blood pressure showed no appreciable change throughout the hospital stay. The white-cell count was 9500 on the 2nd hospital day, 12,300 on the 3rd day and 10,000 on the 4th day, varying between 6700 and 11,000 on the 5th, 6th and 7th days. The neutrophil count remained between 55 and 69 per cent, with 2 to 4 per cent eosinophils on the 5th, 6th and 7th days. Daily urine tests remained negative except for an olive reaction to Benedict's solution on one occasion.

The rash responded in much the same way as when serum is successfully administered. Several areas that were petechial gradually regressed, leaving small brown spots on the skin. The macules gradually faded out and were completely gone within 5 days of entry. Response to the drug was prompt and gratifying. Blood agglutination tests taken 10 days after admission were reported as follows: Agglutination for *Proteus vulgaris* (strain X19) is positive in a dilution of 1:640 and agglutination for Rocky Mountain spotted fever is positive in a dilution of 1:16; the test for endemic typhus is negative.<sup>5</sup> Bacteriologic examination of the blood on August 19 showed that the complement fixation test for Rocky Mountain spotted fever was positive in a dilution of 1:64. The test for endemic typhus was negative.

## DISCUSSION

Although blood concentrations of para-aminobenzoic acid were not determined, the patient's response to this medication is considered to have been prompt and gratifying. This case responded in the same way as those in which antiserum is successfully used.<sup>6</sup> In our experience there have been no rapid recoveries of the disease when specific measures were not employed early.<sup>8</sup>

## SUMMARY

A case of Rocky Mountain spotted fever treated successfully with para-aminobenzoic acid is presented. No toxic effects to the drug were noted.

## MEDICAL PROGRESS

### ALLERGY

WALTER S BURRAGE, M D \*

BOSTON

THE year 1947 was marked by an ever-increasing number of papers on allergy in the medical literature. These appeared not only in journals devoted to this specialty itself but also in a wide range of other medical and scientific periodicals. This broadening of the scope of allergy has not been confined to the clinical problems of the allergist, the internist, the dermatologist or the pediatrician. It has spread into the realms of pathology, biochemistry, pharmacology, immunology and immunochemistry. Investigators in these basic sciences of medicine have done much to increase the understanding of allergic reactions and to suggest the possible importance of this type of mechanism in diseases other than such commonly recognized allergic disorders as asthma and hay fever. This gradual infiltration into allied fields has helped to extend the horizons of allergy both from a practical and from a potential standpoint. It has also made it necessary for recent reviewers to confine themselves to consideration of but a few aspects of allergy at a time.

The present paper is limited to the following topics of general interest that have shown signs of progress in the field of allergy during the past year: a review of the reviews, modern immunologic and pathological concepts of allergy, histamine and antihistaminic drugs, and emotional factors.

#### REVIEWS

Recent general reviews have covered many branches of the literature. Kaplan and Ehrlich<sup>1</sup> have dealt with various aspects of hay fever. The subject of respiration has been covered by Brown,<sup>2</sup> with emphasis on several phases of this complicated mechanism, which is important to allergy.

Boyd<sup>3</sup> has reviewed recent developments in the field of immunity from the standpoint of a chemist but with special reference to the interests of the allergist, discussing the interaction of antibodies with antigens or haptens. Kabat<sup>4</sup> points out the immunochemical difficulties involved in the study of the quantitative aspects of this type of human allergic reaction. Cooke,<sup>5</sup> in discussing the immunology of allergy, provides an immunologic classification dividing such reactions into two types: the immediate or wheal-forming type, which may be of either the induced or the spontaneous variety,

and the delayed immunologic reaction, which produces an inflammatory response of the tuberculin, the dermatitic or the vascular type. Of general interest is his comment that an antigen-antibody mechanism has not been demonstrated in most of the diseases of the delayed or inflammatory type of reaction. Such a mechanism, however, is usually operative in immediate or wheal-forming disorders, such as serum disease, seasonal hay fever and extrinsic asthma.

Drug allergy has been well reviewed by Dragstedt<sup>6</sup> and by Sherman.<sup>7</sup> The latter emphasizes the point that in cases of allergy due to non-protein drugs, circulating antibodies are demonstrable only in rare cases.<sup>8</sup> Skin tests, with the exception of patch tests in contact dermatitis, are therefore of no value. In sensitization due to protein drugs or gums, however, circulating antibodies can usually be demonstrated. In such cases, skin tests by the scratch or intradermal methods may be helpful. A further point is not always appreciated. Drug fever, leukocytosis, arthralgia, lymphadenopathy and many types of skin reactions, as well as the usual allergic symptoms, are often due to drug sensitivity. The *modus operandi* of drug allergy is still under debate but is worth brief consideration. Studies by Landsteiner<sup>9</sup> and others have demonstrated that simple chemical compounds can combine with proteins and act as haptens, thereby determining the specificity of antibody reactions. This theory has helped to correlate crystalloid drug sensitivity with the more familiar protein sensitization. Chase,<sup>10</sup> however, has recently been able to sensitize guinea pigs with repeated intradermal doses of simple chemical compounds dissolved in olive or corn oil. Transfer of serum from such prepared animals to skin sites on normal guinea pigs was successful in sensitizing the latter. When such sites were tested with the original chemical, immediate wheal-forming positive reactions were obtained, often with pseudopods. Chase<sup>11</sup> also succeeded in preventing this sensitization by feeding the same chemical to guinea pigs prior to repeating the experiment described above. These observations are important in that they suggest that drug allergy may operate along the paths of the better known antigen-antibody mechanism. Further observations from the immunologic and biochemical standpoint were made and dis-

cussed by Frazier and Small<sup>12</sup> in their consideration of allergic dermatitis

Excellent progress reports have appeared within the past year in pediatric allergy by Glaser,<sup>13</sup> miscellaneous allergy by Halpin<sup>14</sup> and dermatologic allergy by Baer and Leider.<sup>15</sup> Stevenson and Alvord,<sup>16</sup> in an analysis of allergy of the nervous system, point out that headache, somnolence and convulsions, as well as signs of focal or general disease of the central or peripheral nervous system, may be produced by hypersensitivity. Rackemann,<sup>17</sup> in a scholarly review of the 1946-1947 literature of allergy has discussed many basic and controversial concepts and has summarized several lines of progress. Unger and Gordon<sup>18</sup> have presented a critical review of the domestic and foreign literature on asthma for the same period.

#### PATHOLOGY

The recognition of characteristic histologic changes in various types of allergic disease is recent and one of the more interesting if not the most clinically valuable advance in allergy. According to Bohrod's<sup>19</sup> classification, the results of tissue injury may be anaphylactoid, necrotizing or granulomatous, depending upon various factors, which include the strength of the inflammatory stimulus, the responsiveness of the host and the velocity and the duration of the reaction. The histologic picture varies with the type of lesion. The simplest form of the immediate wheal-like reaction presents a picture characterized primarily by exudative changes such as edema and swelling of collagen fibrils. The diseases that bring this about comprise the common allergic syndromes seen in practice. The reactions are usually mild in intensity and brief in duration and leave the tissues without permanent damage. The granulomatous lesions, on the other hand, are the result of inflammation and cause more permanent damage. Their essential structure consists of a central area of necrosis surrounded by proliferative reticuloendothelial cells, which often assume a radial, palisaded arrangement. Necrotizing lesions likewise destroy tissue. They are characterized by diffuse necrosis involving parenchymal cells, interstitial tissue and vascular structures.

Rich<sup>20</sup> was a pioneer in such pathological studies. He found lesions resembling those of periarteritis nodosa in patients who had died at Johns Hopkins Hospital of serum sickness following sulfonamide therapy. More recently he<sup>21</sup> has pointed out 32 fatal cases in that hospital with similar diagnoses occurring since the advent of the sulfonamides, in contrast to 6 such deaths during all previous years. Gregory and Rich<sup>22</sup> have produced comparable lesions in animals by the injection of egg albumin, and Selye<sup>23</sup> by inoculation of hormone extracts and later by exposure to cold.<sup>24</sup> From the diversity of stimuli that can produce characteristic lesions similar to those found in diseases known to be aller-

gic, it seems evident that an antigen-antibody mechanism is not always essential. Furthermore, similar types of histologic lesions have been described in diseases not considered to have more than a bowing acquaintance with clinical allergy. Among these are disseminated lupus erythematosus, scleroderma, dermatomyositis, Loeffler's syndrome, rheumatic fever and rheumatoid arthritis. Klemperer,<sup>25</sup> in a recent review of this subject, agrees that whereas certain pathologic lesions characterized by collagen swelling and vascular damage are highly characteristic and their presence suggests allergy as a possible cause, they are not specific for the allergic response and are therefore not of diagnostic clinical value.

Periarteritis nodosa has stimulated interest not only from the pathological but also from the clinical standpoint. Elkeles<sup>6</sup> emphasizes the conception that this disease may be an extreme degree of vascular allergy and likewise calls attention to the great variety in the clinical picture including fever of the remittent type, tachycardia, polyneuritis, polymyositis, albuminuria, cylindruria, hypertension, blood eosinophilia and asthmatic attacks with bronchitis. Contratto<sup>27</sup> described 2 cases, 1 in a man with active pulmonary tuberculosis in whom, at different times, biopsies of the lymph nodes showed first periarteritis and later tuberculosis. Bergstrand<sup>28</sup> accents the morphologic similarity between periarteritis nodosa and the transitory infiltration of the lungs in Loeffler's syndrome. Two cases of this disease are presented by Alpper<sup>29</sup>, ragweed-pollen sensitivity was considered to be the etiologic factor in 1. The other, in an asthmatic patient, was characterized by two successive and recent attacks and one probable attack four years previously. Henderson and Pierce<sup>30</sup> have stressed the transitory nature of the focal pulmonary lesions in this disease as demonstrated by serial x-ray films. Tropical eosinophilia falls in the same group. It is important that this disease may be relieved, as in Irwin's<sup>31</sup> 2 cases, by treatment with arsenicals.

#### HISTAMINE AND ANTIHISTAMINIC DRUGS

The greatest clinical advance in allergy in recent years has been provided by the antihistaminic drugs. Their development is an outgrowth of inquiries into the role of histamine in allergy. These studies were initiated in 1910 by Dale and Laidlaw,<sup>32</sup> who noted the similarity of the action of histamine and the manifestations of anaphylactic shock in animals. On the basis of the histamine theory, various efforts have been made within the past decade to counteract the effects of this drug. The first of these was by attempted desensitization with repeated injections of histamine. This was followed by a wide use of histamine azoprotein "hapamine" with the hope that a conjugate might stimulate antibodies more easily than treatment with histamine itself. Histaminase was next offered

as a possible means of destroying histamine, but this enzyme failed in vivo to live up to its promises in vitro. None of these methods of treatment have been accepted with more than limited enthusiasm. The antihistaminic drugs provide a different approach to the problem, they have a competitive chemical action against histamine. Loew,<sup>33, 34</sup> in reviews of the pharmacology of these compounds, states that their effectiveness appears to be definitely related to their ability to diminish or block the

‡Suggested superiority over the other drug.

effects of histamine upon vascular and visceral smooth muscle and permeability of capillaries. He concludes that none of the evidence suggests that these drugs influence the antigen-antibody reaction. Rose<sup>35</sup> postulates that patients with allergic diseases demonstrating histamine effects must have two operative factors. The first is that the tissues must be hypersensitive to histamine, and the second that there must be a shift of this substance from the intracellular or inactive form to the extracellular or free state and that small amounts of histamine may thus be continually released, producing local effects, and then rapidly removed from the blood by means of the kidneys. Feinberg and his associates<sup>36-42</sup> have been pioneers in reviewing the experimental and therapeutic status of the antihistaminic drugs. Reports of clinical results with the most widely known of these medications, benadryl and pyribenzamine, have now been recorded in several thousand cases. Such accounts include the percentage effectiveness of either or both drugs in various conditions, their comparative merits and the frequency of their side reactions. Carefully controlled series of over 100 cases in each study have been published by

Feinberg et al, Henderson and Rose,<sup>43</sup> Blumenthal and Rosenberg,<sup>44</sup> Wagner,<sup>45</sup> Arbesman and his co-workers,<sup>46, 47</sup> the American Academy of Allergy,<sup>48</sup> Loveless and Brown,<sup>49</sup> Waldbott,<sup>50</sup> O'Leary and Farber,<sup>51</sup> Levin<sup>52</sup> and Todd.<sup>53</sup>

Loveless,<sup>54</sup> in a recent comparative study based upon a survey of twenty-six clinical reports from the literature, summarizes the results of trials in over 2000 cases with pyribenzamine and in nearly 1500 with benadryl, as well as a percentage tabulation of side reactions (Tables 1 and 2).

It is obvious from these tables and from compilations by other reviewers<sup>17, 36</sup> that benadryl and pyribenzamine provide temporary relief in varying degrees for many types of allergic manifestations. It is equally evident that side reactions are common. These are usually transient in nature and are seldom serious or of more than temporary concern either to the patient or to the physician. Occasionally, however, more serious reactions occur. Epstein<sup>55</sup> reported the development of eruptions in 2 patients with atopic eczema while they were taking pyribenzamine. One eruption was of the eczematoid type, the other resembled

pityriasis rosea. Both cleared with the withdrawal of the drug and recurred on its readministration. Blanton and Owens<sup>56</sup> recorded the appearance of agranulocytosis in a seventy-three-year-old woman after eight weeks of therapy for urticaria with pyribenzamine. After withdrawal of the drug and treatment with penicillin, the blood and clinical pictures returned to normal. Urinary incontinence, involuntary spastic movements of the extremities, slurred speech and irrational behavior were noted by Weil<sup>57</sup> in a boy of three and a half after two doses of 50 mg of Benadryl and a third of 100 mg six hours later. Sternberg<sup>58</sup> describes a twenty-two-year-old nurse who was hospitalized for hysteria after one week's treatment with daily doses of 200 mg of benadryl. On withdrawal of the drug she became normal. Geiger, Rosenfield and Hartman<sup>59</sup> reported palpitation, dimmed vision, malaise, drowsiness, heartburn and nausea after a daily total dose of 300 mg of benadryl given over a three-

day period. After the next dose of 50 mg, the patient was found unconscious. All symptoms subsided with withdrawal of the drug. With the exception of the unconsciousness, they all recurred when the same dosage of benadryl was administered a week later. The dangers of self-medication are illustrated by Borman,<sup>50</sup> who recounts the case of an eighteen-year-old girl who obtained excellent relief of hay fever and asthma from her first day's treatment with two 50-mg benadryl capsules. Encouraged to increase her own dose, she took forty capsules (2000 mg) within the following three days. She became drowsy and irrational but with forced fluids completely recovered within forty-eight hours. It was believed that her judgment may well have been affected by the first two capsules of benadryl.

I recently observed the following case, as yet unreported.

A 25-year-old housewife, referred for study of chronic vasomotor rhinitis, had previously been given 200 mg of pyribenzamine daily for treatment of persistent nasal obstruction. She was apparently normal in other respects. During the first 10 days of this medication she obtained relief from the nasal symptoms but became increasingly nervous, sleepless, absent minded and depressed. She even contemplated suicide. At times she forgot how to cook or how to set the table. She also neglected now and then to feed her children or to get her husband's dinner upon his return in the evening. She lost 14 pounds in 10 days. On the 11th evening of medication, her husband entered the kitchen to find the patient finishing the last of a new bottle of twenty-five 50-mg pyribenzamine tablets purchased that day. Her physician was on vacation but another doctor was called. He prescribed an emetic, with resultant evacuation of the stomach contents. During the next few days the psychotic symptoms gradually disappeared and at the end of a week the patient felt perfectly normal except for nasal obstruction which had recurred. She therefore decided to resume the pyribenzamine in doses of 200 mg daily. All the former symptoms slowly returned. Five days later she was visiting one of her children sick in the hospital when the child's physician arrived to find the mother sound asleep at her daughter's bedside. Pyribenzamine was immediately stopped with a gradual return to normal. With the reappearance of nasal obstruction, a 5-day trial was given to theophylline, one of the newer antihistaminics, which was prescribed in amounts of two tablets daily. This therapy was followed by sustained exhilaration and a feeling as if the patient were walking on air or flying. Reduction of the dose to one tablet did not improve the situation so that this medication was discontinued, with final disappearance of the untoward symptoms.

The satisfactory clinical response to the earlier antihistaminic drugs such as benadryl and pyribenzamine, as well as the obvious disadvantages of their side actions, has prompted much investigation in an effort to obtain more powerful but less toxic products. The trade names of over thirty such antihistaminic substances are already a matter of record. A number of these are having extensive therapeutic trial. Reports have appeared upon clinical results with neo-antergan,<sup>51</sup> antistine<sup>52</sup> and decapryn.<sup>53</sup> Halpern<sup>54</sup> has been working on the thiodiphenylamine derivatives, of which 3015 RP and 3277 RP are the most promising. This new chemical series is reputed to be less toxic and more active than earlier ones. It is too early to evaluate

these or the many other antihistaminic drugs that will appear upon the market within the near future.

As Feinberg,<sup>55</sup> Burrage<sup>56</sup> and others<sup>57</sup> have stressed, the histamine antagonists are valuable adjuncts to the treatment of allergic disease, but they do not immunize the patient, nor is their benefit more than a brief one. It is obvious that their administration is attended by frequent side effects of varying degrees of severity. Not enough time has elapsed to rule out the possibility of more remote toxic effects.

#### EMOTIONAL FACTORS

In any large group of patients with allergic manifestations the etiologic factors remain obscure in a considerable percentage even at the end of routine allergic studies. Mitchell et al.,<sup>58</sup> bothered by this common observation, analyzed a group of 600 consecutive cases of representative types of allergy. This series was divided into positive skin reactors whose symptoms such as hay fever and extrinsic asthma could be correlated with proved causative factors and non-reactors with perennial vasomotor rhinitis, "intrinsic" asthma and chronic urticaria. Early age of onset was evident in the reactor group in contrast to a late beginning of symptoms in the other. This in itself is not unusual, since many observers, including Rackemann,<sup>59</sup> have pointed out that asthma starting before the age of thirty is a different disease from that which begins after forty. In the nonreactor group, there was a 2:1 predominance of females with symptoms most common in the third, fourth and fifth decades — a time in life in which the authors considered conflict and situational factors to be related to the production and persistence of allergic symptoms. Subsequently, 1129 cases of perennial asthma observed over a ten-year period were classified according to the major etiologic factors. It was found that 1 out of every 5 of these cases (22.7 per cent) were diagnostic and therapeutic failures. One hundred such year-round cases were next selected for careful individual review, and it was again discovered that approximately the same number (21 per cent) showed signs of psychologic maladjustment in view of the expressions of confusion, hostility, fear, guilt and so forth that were brought out in prolonged and careful history taking. These characteristics were in sharp contrast to the clear-cut, succinct, unemotional statements common in the reactor groups. Gleebe and Kerr<sup>61</sup> presented 4 such cases in detail, illustrating the importance of psychogenic elements in 1 case of chronic headache, in 1 of chronic urticaria and in 2 of primarily intrinsic asthma. They agreed with the previous authors that the role of the emotions in causing, precipitating and aggravating latent allergic sensitization will be adequately recognized and that the study, diagnosis, treatment and relief of allergic manifestations will be substantially furthered if

history taking is broadened to include psychologic events, particularly if these events are correlated with the somatic reactions at the time of occurrence. Mitchell and Curran<sup>69</sup> have reviewed the earlier literature and stressed again the advisability of the sensitive, nondirect method of approach to this type of patient rather than one of abrupt questioning. This technic has seemed in numerous cases to reveal useful psychologic data, with the production of a state of release and attendant psychologic adjustment and symptomatic improvement.

Henderson<sup>70</sup> believes that asthma should be conceived of primarily as an organic disease based on disturbed respiratory physiology—the result of allergic influences—in which psychic and emotional factors may indeed be important in precipitating, modifying or inhibiting attacks in patients already the subjects of asthma. Billings<sup>71</sup> discusses 12 patients with bronchial asthma from the psychogenic standpoint. He warns that the establishment of such an etiology requires relatively long psychotherapeutic guidance and that the more diffuse the complaints, the less satisfactory the therapeutic results are likely to be. Cormia<sup>72</sup> has classified the psychosomatic dermatoses, including such disorders of allergic interest as urticaria, dermatographism, pruritus and atopic and contact dermatitis. He outlines a combined dermatologic and psychiatric approach, which he believes lends itself well to all but the more long-standing recalcitrant conditions for which prolonged psychoanalysis is indicated. Metzger<sup>73</sup> recognizes the importance of the emotions and discusses a case. Fabricant<sup>74</sup> deliberately induced fright and emotional upsets in 3 susceptible subjects during determination of the nasal reaction, with a resultant rapid shift from slightly acid (pH 6.5) to alkaline (pH 7.3). A similar type of observation was made by Wolff,<sup>75</sup> who noted vasoconstriction of the nasal mucous membranes of a boy when he was frightened. Nasal congestion appeared, however, when fear disappeared and rage took its place. MacLean,<sup>76</sup> and Swanton,<sup>77</sup> both in Australia, have presented cases to illustrate the psychophysical interreactions in the asthmatic patient. Although Salter<sup>78</sup> emphasized the importance of the psychogenic factor in asthma almost seventy years ago and many observers are now willing to agree to its possible role in allergy, comparatively few papers have appeared upon the subject up to recent years, and even fewer large series of cases have been carefully studied from this angle. I believe that in no case should psychologic study replace but rather that it should more frequently supplement other generally accepted methods of allergic investigation. I predict, moreover, that there will be a wider acceptance of the importance of this approach in certain types of allergic disease.

## CONCLUSIONS

The field of allergy has now become so broad that its concepts must be integrated with those of the fundamental medical sciences as well as with those of its parent internal medicine. The skin test has ceased to be the only trade-mark of the allergist. Advances in allergy are often initiated, developed and reported in other fields. Progress in allergy can no longer be reviewed in its entirety.

The modern role of pathology in allergy is illustrative of this modern trend. Recent pathological studies suggest a common histologic denominator between diseases now known to be allergic and several conditions with similar histology but with no clinical characteristics of allergy. Future investigations may point the way to some common causative mechanism in these diseases.

A review of the antihistaminic drugs records a definite advance in allergic therapy. Caution is advised that their administration be carefully supervised, and it is recommended that they be employed to supplement rather than to replace well tried principles of allergic management.

The psychologic approach to the etiology of otherwise unexplained allergic disease marks another step forward. A broader acceptance of this diagnostic and therapeutic aid to allergy is urged and predicted for the future.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

### Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

BENJAMIN CASTLEMAN, M.D., *Associate Editor*

EDITH E. PARRIS, *Assistant Editor*

#### CASE 34221

##### PRESENTATION OF CASE

A sixty-two-year-old electrician entered the hospital complaining of malaise and exhaustion.

Five days before admission he noted abdominal rumbling and loose stools. He felt that he was about to have an attack of diarrhea. He went to the basement in the dark to take a drink of whisky to relieve this and by mistake picked up a bottle of carbon tetrachloride and drank about an ounce. As soon as he tasted it he spat it out and induced vomiting with his finger. He vomited numerous times during the following several hours and also had repeated watery stools. Later that evening he felt better although somewhat weak. He slept well but on the following morning was so weak that he stayed home from work. During the following two days he continued to have severe anorexia, taking very little food or drink. In addition, he noted an intermittent, dull, aching pain in the lower back, "between the hips," and soreness in the right upper quadrant. His wife noticed that his eyes were bloodshot and the surrounding tissues swollen. The urinary output decreased to little more than a few drops each day. During the twenty-four hours preceding entry all symptoms seemed to decrease in severity. He felt somewhat stronger, and the pain in the back diminished. He passed about an ounce of normal-looking urine during this twenty-four-hour period. There had been no jaundice, chills, fever or hematuria.

The past history revealed an attack of acute nephritis at the age of twenty-two, necessitating eight weeks of convalescence at home. There had apparently been no residua. There was no known albuminuria or hypertension. The patient denied excessive alcoholic intake.

Physical examination revealed a well developed, slightly obese, restless man in no acute distress. There was a peculiar odor to the breath, which was described as being neither characteristically uremic nor mousy. The periorbital tissues and conjunctivas were edematous and hemorrhagic. The optic fundi were not remarkable. There was no icterus of the skin or scleras. The lungs were clear, and the

heart was of normal size without murmurs. The liver edge, which was smooth, soft and moderately tender, was palpated two or three fingerbreadths below the costal margin. There was percussion tenderness over both costovertebral angles. The extremities were normal.

The temperature was 98.6°F, the pulse 80, and the respirations 25. The blood pressure was 165 systolic, 90 diastolic.

The urine was cloudy and gave a ++++ test for albumin, the specific gravity on two specimens was 1.010. The sediment contained 20 to 30 white cells and 15 to 20 red cells per high-power field. In addition, 6 to 8 epithelial cells, loaded with fat droplets, and occasionally large granular casts were seen. The red-cell count was 4,320,000, and the white-cell count 8700, with 72 per cent neutrophils. A stool was negative for occult blood. The non-protein nitrogen was 250 mg per 100 cc. The prothrombin time was 27 seconds (normal, 15 seconds).

The patient seemed to do fairly well in spite of the fact that he voided only 75 cc of urine during the first hospital day. During the second and third days his condition deteriorated, and he gradually became drowsy. Though he passed 360 cc of urine on the third day, the urinary output dropped again on the fourth to 240 cc. Moist rales developed at the right base. On the fifth day there was an acute onset of severe dyspnea, restlessness and disorientation, which continued for two hours. Finally convulsive and twitching movements of the trunk and extremities appeared, and the patient died.

##### DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB: "He went to the basement in the dark to take a drink of whisky and by mistake picked up a bottle of carbon tetrachloride and drank about an ounce." It is a source of wonder to me that it is stated that this man was not an alcoholic even though he went to the dark cellar to get a drink of whisky and drank a whole ounce of carbon tetrachloride before he tasted it.

DR. WILLIAM W. BECKMAN: The patient took whisky for medicinal purposes whenever he was ill, he kept the bottle in the basement.

DR. AUB: I suspect that he often anticipated that he was going to have diarrhea.

The soreness in the right upper quadrant is important. Carbon tetrachloride affects the kidneys and liver, and yet that is the only note in relation to the liver soreness.

This case is typical of death from carbon tetrachloride poisoning. There is no use considering anything else. In my opinion this man died of carbon tetrachloride poisoning. Why on the tenth day, I do not know. There are cases in the literature in which the patient died on the tenth day, and this is earlier than death occurring from bichloride of mercury. The difference, I suppose, lies in the fact that carbon

tetrachloride poisoning involves the liver as well as the kidneys. Though there is very little evidence that the liver was involved in this case, one should be very suspicious of it. There are not an enormous number of deaths from carbon tetrachloride poisoning recorded in the literature. Carbon tetrachloride is not a very hazardous industrial solvent. It can be breathed in fairly high concentration without damage because most of it comes out by the lungs. Many of the deaths are due to swallowing of the poison. They follow the use of carbon tetrachloride as an anthelmintic in doses of 2 or 3 or at most 4 cc. As a result of such medication a fair amount of jaundice develops, with acute yellow atrophy and death. Such a course has occurred in people who are alcoholics or who drink alcohol with the carbon tetrachloride, and in people who take a good deal of fat the fat escorting the carbon tetrachloride across the intestinal tract. There are a sufficient number of deaths from carbon tetrachloride to cause it to be avoided as a drug. The deaths that occur are characteristic of that in the case under discussion, except that most of the patients have had jaundice. This patient did not have jaundice. Anne Minot\* who worked with us on lead poisoning, found that lethal doses did not kill a dog if calcium gluconate was given intravenously. Calcium and glucose relieve the strain on the liver sufficiently so that the animal did not die when this was given. Most of the animals that did die in her series died from bleeding in the gastrointestinal tract. This patient had no evidence of bleeding, but the dogs in the experiments died of hemorrhage, through either acute ulceration or duodenal ulcer. Carbon tetrachloride causes injury to both the liver and the kidney. The liver is affected mostly at the inside center of the lobule, the outside of the lobule being less involved. This patient showed an enlarged liver and an elevated prothrombin time, but no jaundice. Is autopsy going to show any abnormality? In spite of the fact that he said that he went to the cellar because he did not feel well, he probably consumed a fair amount of alcohol, and I guess that the carbon tetrachloride did him more damage because of the alcoholic habits. On the basis of that, I think that he had a moderate amount of cirrhosis and a moderate amount of acute yellow atrophy. There is no good evidence for such a statement except that he had an enormously high nonprotein nitrogen. I should like to know what the amino acid content of the plasma was. I assume that the determination was not made.

Dr. BECKMAN: No, it was not.

Dr. AUB: If the patient had acute yellow atrophy, the best evidence would have been elevation of amino acids in the blood stream as well as jaundice. Without those data one cannot make the diagnosis of acute yellow atrophy. On the basis of pain in the right upper quadrant and the large liver, and since

carbon tetrachloride usually affects the liver, I shall say that he had a certain amount of liver destruction and acute yellow atrophy, not enough to give jaundice, and that it did not cause his death.

The chief cause of death was injury to the kidneys, which had been previously damaged. Not infrequently carbon tetrachloride affects the kidney as well as the liver, therefore, I expect to find damage to the tubules, severe damage, with acute nephritis, with uremia, convulsions and death. Some edema was probably found in the lungs, particularly the right lower base, which was said to have rales due to the fact although the record does not say so, that he was given much intravenous saline solution and got rid of very little of it by the kidney. I do not believe that caused the edema in the lungs, but it added to it. He died of uremia and, therefore, had convulsions. Why these patients get convulsions previous to death, I do not know. All the cases that I have seen as well as those in the literature have shown that I think that is probably a uremic manifestation. Carbon tetrachloride goes wherever there is fat, and yet there is very little present in the central nervous system. Fatty cells in the kidney are not unusual, because, since the drug is a fat solvent, fat gets free, and the plasma is very apt to be lipemic in this condition. It is one of the ways of knowing whether the carbon tetrachloride is doing damage.

Therapy is not usually discussed at these meetings. I think that most people do not pay enough attention to Anne Minot's suggestion of injection of calcium salts for the liver damage of carbon tetrachloride poisoning. Any patient who has acute yellow atrophy ought to be given calcium and also ought to have glucose, which is very saving of the liver in liver damage. These patients also sustain severe kidney damage. If they survive, they show a surprisingly small residue of kidney damage. The only way I know of saving them is by flooding them with fluid (a course that I suppose was followed in the case under discussion) and also by giving them an adequate amount of alkali to produce diuresis. I am glad that there is no time for further discussion because a number of people would disagree with me. But in my experience, with toxic injury to the kidney, patients do well if large quantities of alkalies are given to produce diuresis. I have seen a number of patients with bichloride poisoning who finally urinated when given large amounts of sodium bicarbonate in intravenous injections. If these people can urinate and get over the uremia, a number of them recover with surprisingly small deleterious effect on the kidneys.

Dr. TRACY B. MALLORY: Dr. Aub has made the diagnosis seem obvious. Has anyone any questions, or does anyone take exception to that diagnosis?

Mr. WILLIAM Kiyasu: What is the antidote for carbon tetrachloride poisoning — lavage?

\*Alliot A. S. Mechanism of hypoproteinemia produced by  $\text{CCl}_4$  in a dog. Carbon tetrachloride poisoning. It is relieved by calcium medication. *J. Pharmacol. & Exper. Therap.* 43:295-315, 1911.

DR AUB After the drug has been swallowed, I suppose so. It is absorbed very rapidly, being a lipid solvent. I suppose that a stomach wash is indicated, but that does not help much unless done very promptly. Even after repeated vomiting, enough of the drug may still be retained to do damage. In bichloride of mercury, for instance, enough will be retained even after the patient has vomited continuously for an hour. I think the stomach should be washed, but castor oil or alcohol, which might further help the absorption, should not be given.

DR BECKMAN All I can say is that this emphasizes the value of these exercises, because when I had this patient on the ward as nearly as I could tell he had swallowed no carbon tetrachloride at all, but I am obliged now to admit that he must have. I stood out against the whole field, including the patient, on the diagnosis of carbon tetrachloride poisoning.

FIGURE 1

I thought that it was an exacerbation of the nephritis that he had had forty years previously and that he had developed high blood pressure and severe uremia of which he died. But I think that I was wrong.

#### CLINICAL DIAGNOSIS

Acute nephritis

#### DR AUB'S DIAGNOSES

Carbon tetrachloride poisoning, with renal and hepatic damage

Uremia

Pulmonary edema

#### ANATOMICAL DIAGNOSES

*Carbon tetrachloride intoxication*

Lower-nephron nephrosis

Central necrosis of liver, acute

Pulmonary atelectasis, both lower lobes

Arteriosclerosis, generalized, moderate

#### PATHOLOGICAL DISCUSSION

DR MALLORY The autopsy findings to my mind conclusively proved that Dr Aub was correct. The

FIGURE 2

first view of the liver was almost conclusive, and at post-mortem examination I was struck with the appearance of the liver. It was rather small, and its surface was yellow, with closely sprinkled, bright-

FIGURE 3

red dots. On cut surface the central half of every lobule was depressed and red. The microscopical sections showed complete loss of the liver cells in the central half or two thirds of the lobule (Fig 1). At

the periphery many of the surviving liver cells showed fat vacuoles, another phenomenon characteristic of carbon tetrachloride poisoning. The portal areas, in contrast, were quite normal and showed no cellular infiltration such as one sees in hepatitis.

The kidneys revealed a pigment nephrosis indistinguishable from that of transfusion reaction, which is what one characteristically sees in carbon tetrachloride poisoning. The picture differs from bichloride poisoning, in which the proximal convoluted tubules are injured. Here the straight tubules of the medulla are filled with hemoglobinuric casts (Fig. 2). The cortex showed dilated proximal tubules, but no cellular degeneration, and, incidentally, fat stains of the kidneys did not show any fat. On the other hand, the distal convoluted tubules disclosed a severe grade of degeneration. Figure 3 demonstrates one of the phenomena that we see characteristically in the lower-nephron lesion—a tubule, the wall of which has been destroyed, and there is a cast in process of extension into the stroma, producing a foreign-body type of granuloma in the stroma. The entire picture is like that of a kidney injured by transfusion, crush or sulfonamides. The combination of such a renal lesion with the liver lesion is very unusual in anything except carbon tetrachloride poisoning. In the Army there were a considerable number of cases of this sort that could be surely attributed to carbon tetrachloride injury. Not infrequently the renal symptoms predominated so far over the hepatic symptoms that the latter passed unnoticed.

**DR. AUB.** If the patient could have weathered the acute illness, what would the end result of the kidney lesion have been?

**DR. MALLORY.** I believe that there would have been absolute restitution to normal. There are not a great many anatomic observations on record. Kinney observed a case at the Peter Bent Brigham Hospital last year in which the patient died of homologous serum jaundice after three months, having successfully weathered a transfusion reaction in the course of which he had renal insufficiency. That kidney, so far as could be determined anatomically, was normal. There are a fair number of patients who survive a lower-nephron lesion who have been studied functionally. Those kidneys re-establish normal function in approximately two to four months.

## CASE 34222

### PRESENTATION OF CASE

A fifty-five-year-old Finnish woman entered the hospital because of loss of weight, easy fatigability and the appearance of an abdominal mass, which was gradually increasing in size.

About three months before entry the patient began to lose her appetite and to feel tired. During this

period she lost about 25 pounds in weight. Two months before entry she first noticed the appearance of a mass in the abdomen. She claimed that the mass had increased considerably in size since that time. One week prior to admission she began to vomit after the ingestion of any foods or liquids. This had persisted at intervals until entry. The bowel movements had been regular until several days before admission, at which time she had several bouts of nonbloody diarrhea four to six times daily. On the day of entry the bowel movements were normal. She had never had any abdominal pain, and the mass had not been tender.

Thirty-one years before entry she had an operation for a "dropped stomach," and thirteen years previously, while she was in Finland, a hysterectomy was performed. She had two children, aged sixteen and twenty-five years, both were living and well.

The only positive physical finding was the presence of a firm irregular mass (20 by 15 cm.) located mainly in the left midabdomen but extending for a short distance to the right of the midline beneath the umbilicus. The lower border of the mass projected into the pelvis on the left side. It was freely movable and nontender. The abdominal wall was flaccid, and it was possible to pick up the tumor and move it several centimeters in any direction. The greatest mobility was from side to side. Pelvic examination revealed no masses in either vault. The uterus was absent. The lower border of the tumor on bimanual examination could be felt at the pelvic brim, more prominently on the left.

The temperature, pulse, and respirations were normal. The blood pressure was 142 systolic, 80 diastolic.

Examination of the blood showed a hemoglobin of 11.8 gm. and a white-cell count of 7800, with 83 per cent neutrophils, 5 per cent lymphocytes, 6 per cent monocytes, 3 per cent eosinophils and 3 per cent basophils. The platelets were normal. The nonprotein nitrogen was 26 mg. per 100 cc.

A barium enema was done on the second hospital day. The colon filled readily without evidence of obstruction. There were numerous small diverticula scattered throughout the sigmoid. A tumor mass was observed in the left side of the abdomen. It compressed the left side of the transverse colon but did not appear to be attached to the colon. The remainder of the colon showed no abnormality. The cecum was freely movable, and the terminal ileum filled readily and appeared normal. The findings were consistent with a mass extrinsic to the large bowel.

On the third hospital day an exploratory laparotomy was performed.

### DIFFERENTIAL DIAGNOSIS

**DR. MARSHALL K. BARTLETT.** In summary, this is the problem of a fifty-three-year-old woman with a three months' history of loss of appetite, weight loss (25 pounds) and a mass in the abdomen of at

least two months' duration, which had increased in size during that time. A week prior to entry she began to have vomiting and intermittent diarrhea. The only helpful physical finding on admission was the presence of a firm, irregular and quite movable mass.

May we see the x-ray films?

DR. STANLEY M. WYMAN: These are two films from the barium examination of the colon. The transverse colon is unusually low in position. This film shows compression of the left transverse colon without definite involvement of the mucosa. There is a suggestion of faint outlining of the mass in this position. It lies higher than I thought from the description. Diverticula are present in the sigmoid. The terminal ileum is not well seen. I can see no other masses, and there is no evidence of calcification in this area.

DR. BARTLETT: Can you tell whether it is above or below the transverse colon?

DR. WYMAN: It seems to be above.

DR. BARTLETT: Can you see the kidney shadow and the spleen?

DR. WYMAN: The left kidney shadow can be seen at this point. The lower pole is outlined well. The upper pole cannot be seen. The spleen is outlined and seems to be within normal limits in size and shape. The liver is not remarkable. The right kidney is probably essentially normal.

DR. BARTLETT: That really helps me somewhat, because it rules out certain diseases that I had thought of considering, not having seen the x-ray films and not knowing whether the tumor was above or below the transverse colon. They fairly well rule out the possibility that this was an ovarian cyst, which if present, should have been below the transverse colon. There are various other things against that possibility. I think it would be unlikely that an ovarian cyst would cause nausea and weight loss and gastrointestinal symptoms, unless it was a malignant cyst with extensive metastases, and of course the pelvic examination does not give any hint that this was connected with the pelvic organs. In spite of the fact that a hysterectomy had been performed, the ovaries could have been left behind. We have no information about that. All in all, a cyst of the ovary seems like a remote possibility.

The normal shadow of the spleen, I think, is adequate to rule out the possibility that this was a tumor of the spleen. Such a tumor arising in the

spleen would probably displace the colon differently. Again, it hardly is enough to account for the weight loss and gastrointestinal symptoms on that basis. Along the same line of reasoning, I will exclude the kidney although Dr. Wyman is not quite sure about the kidney.

DR. WYMAN: I think that the lower pole is all right.

DR. BARTLETT: That is even more helpful. I shall rule out the possibility of kidney disease. An intravenous pyelogram, of course, would give further evidence on that point, but I take it that the kidney was not seriously considered as the source of this woman's trouble or such an examination would have been done. I dwelt at some length in my mind on that possibility because I had recently been caught at a conference at another hospital on a pelvic tumor that I thought was an ovarian cyst and it proved to be a solitary cyst in an ectopic pelvic kidney.

What other possibilities are there? I thought about the possibility of a lesion in the mesentery of the small bowel, but, again, a tumor in that region would not lie above the transverse colon, it would be below it. I shall dismiss it. Anything that I might say about a cyst or tumor in the mesentery of the small bowel can be equally well applied to the large bowel—to the transverse colon—and we might consider that possibility. There are tumors of the colon that attain considerable size. I am thinking of spindle-cell tumors, which become relatively large without causing much in the way of symptoms. There are two general types based on the point of origin: those that arise in the submucosal areas and the ones that tend to invade the lumen and cause obstruction. I feel sure that one would not attain this size and still give a negative barium enema or a barium enema that shows no evidence of obstruction. The subserous type may get big before symptoms appear. They are apt to manifest themselves by bleeding. We have no particular evidence, other than a moderately reduced hemoglobin, that this patient had bled. There was no history of massive hemorrhage by rectum. No examination of the stool is recorded, but there is nothing particular to suggest that she bled by rectum.

How about a cyst of the mesentery of the transverse colon? I think that is a possibility. Those cysts are rare. When they occur they may either be lymphatic in origin or they may be dermoids. They occasionally can be as big as the mass in this case, but not very frequently. I do not believe that all

these lesions would have been described exactly like this one, which was an irregular, firm mass. I think that a cyst of the mesentery of the transverse colon should be smooth. Again, with a cyst in the mesentery of the bowel or even with a subserous tumor arising from the transverse colon, it is rather difficult to account for the anorexia, the weight loss and the other symptoms.

That brings me down to the pancreas. Was this a lesion arising in the pancreas? In favor of that it seems to me, is the fact that pancreatic tumors are notorious for insidious onset, with nausea and weight loss, and perhaps this case would be best explained by something of that type. What kind of lesion of the pancreas would resemble this? I think it was too big for a solid tumor of the pancreas. I do not remember seeing or hearing of a solid tumor of this size behaving in this fashion, because they usually produce more symptoms before they reach this size. How about a cyst of the pancreas? There are various types of cysts. The most common is probably the so-called pseudo-cyst, which is the end result of an inflammatory process or sometimes is the result of trauma. These tumors attain good size, and they lie really extrinsic to the pancreas. They start in but extend outside the substance of the pancreas, so that a pseudo-cyst could be in this location and present this picture on physical examination. These cysts, however, are ordinarily unilocular and smooth on the external surface. Likewise, retention cysts, which presumably result from occlusion of some part of the ductile system of the pancreas, are smooth and do not reach this size. If this was a cyst of the pancreas, it seems most likely that it was a cystadenoma. These cysts are multilocular, so that the external surface is irregular, they attain considerable size, often are benign in the early phase and often become malignant as they progress and grow larger. Such a cyst may be present in various locations. Above the lesser curvature, between it and the liver, is the most common place. The next most common is between the greater curvature of the stomach and the transverse colon, which is where this tumor seems to have been located. The least common point is below the transverse colon, though the cysts can even be present there.

It seems to me, considering the various facts that we have, that a lesion of the pancreas is probably the best diagnosis that I can make. Of the various possible lesions of the pancreas, I think a cystadenoma is probably the most likely.

DR. TRACY B. MALLORY: I am surprised that someone does not try to connect the patient's nationality with the lesion.

DR. BARTLETT: What was her nationality?

DR. MALLORY: Finnish. I knew that we had had an echinococcus cyst not long ago, and as I read over the history, that was my guess, but unfortunately I was not correct.

#### CLINICAL DIAGNOSIS

Ovarian tumor?

Tumor of stomach?

#### DR. BARTLETT'S DIAGNOSIS

Cystadenoma of pancreas

#### ANATOMICAL DIAGNOSIS

*Malignant lymphoma, giant-follicle type, of mesentery of small bowel*

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The preoperative diagnosis was probable tumor of the stomach, but I gather that the surgeons were very uncertain about it. The patient was explored. The ovaries and stomach were both found to be perfectly normal. There was a large mass in the root of the mesentery of the small bowel, which had grown outward at one spot along the mesentery to a point where it involved the wall of a short segment of small bowel. The tumor went rather far posteriorly, but the surgeons were able to feel the kidney and were sure that it was not connected with that. The mass as a whole was impossible to resect, but the small segment of involved ileum was resected, since it was feared that the bowel might soon become obstructed. At operation frozen section was attempted, but it was not possible to say what the tumor was. Our later section showed it to be malignant lymphoma, giant-follicle type, and the patient is now having x-ray treatment.

## THE NOLAN-MILES BILL IN RETROSPECT

AFTER much publicity and rather more than the usual amount of misstatement and raucous vituperation from its opponents, the Nolan-Miles Bill has been referred to a legislative research committee for "further study" (*sic*). This is discouraging to those who have worked long and hard for the passage of this sensible piece of legislation. Perhaps the best the medical profession can do is to review the situation and see what can be done in the future.

There are two classes of opponents to this bill. One consists of a rather small minority of sincere but misguided people. To change the opinion of this group seems an impossible task, even though the evidence is overwhelmingly in favor of the value

of the bill to humanity and to medical research. If this small group had represented the only opponents there would have been no great difficulty in obtaining favorable action. But there is a much larger and a far more vocal group that advances no reasons against the bill other than those of misguided sentimentality. Unfortunately, this group does not confine itself either to facts or to the real purpose of the bill as explained in its wording. These opponents harp continually on the cruel doctor whose sole interest in the passage of this bill is to steal, torture and eventually kill the pet dog of little Willie Jones. They disregard entirely the present laws for the disposal of lost animals, ignoring the fact that annually thousands of animals are put away in a humane manner because no one claims them at the pounds. It is these animals, which are to be destroyed under the law, that the proponents of the bill wish to make available for the fundamental, important and humane purposes of medical research.

W. E. Mullins, in the *Boston Herald* of March 18, has done an outstanding piece of constructive journalism in his report on the Nolan-Miles Bill. He wrote as follows:

Legislators have lost sight of the fact that the responsibility is theirs and not that of the medical profession. The politicians should vote on every bill strictly on merit and not on the noise that is made by organized minorities. Busy doctors should not be required to go several times annually to the legislature to plead for the right thing.

One of the legislators had stated in the press, (*Boston Herald*, March 15, 1948) that, "Doctors can individually advise their legislators on bills vital to the protection and progress of Massachusetts medicine — 'or risk losing them'."

As Mr. Mullins wrote:

The Massachusetts Medical Society sent its official spokesman to Beacon Hill to plead for it. This is an organization of the foremost medical men of this state. Against the considered opinion of this Society that passage is essential to the continuation of medical research, what do we have? We have this opinion: "I do not think it will help medical science."

The opinion quoted came from a physician serving in the legislature.

The Council of the Massachusetts Medical Society is a body democratically elected by the Society to voice its opinions. At a meeting held

shortly before the bill came to the legislature, the Council voted unanimously to go on record as expressing its hearty approval. What more can a legislator want as evidence of approval of the medical profession? To be sure, a vote is a vote (especially in an election year), but even if every member of the Massachusetts Medical Society appeared individually they would still be greatly outnumbered by the very vocal group of opponents. In addition to the official approval of the Council, however, the Massachusetts Medical Society sent to represent it some of the outstanding physicians and surgeons in the Commonwealth and, indeed, in the country.

The medical profession of Massachusetts made great efforts to obtain favorable action on the bill and came near to success. Disappointing and belittling as it is to be subjected to taunts and insults at a public hearing on Beacon Hill, the medical profession must nevertheless take up this added burden for the greater good of humanity and the advance of the profession. It must accept this challenge and by greater effort make its considered opinion heard, and *effectively* heard by those who, in many cases, are swayed only by the number of votes and not by the thought that goes behind a "yes" or a "no." It must do this rather than adopt a defeatist attitude, which would be welcome to its opponents.

One good, at least, has come out of the clamor of the controversy. A public education process has been started, and the need for greater and continuing education has been made apparent.

### MILLIONS FOR DEFENSE

The Council on National Emergency Medical Service of the American Medical Association sponsored in April a conference to consider the defense of America in the event of a general national emergency. Fifty-one persons were present, representing an impressive majority of the state medical societies as well as a number of national associations of allied professions.

Certain important points were brought out during the course of the conference. Such an emergency, should it occur, will apply especially to our

scattered industrial centers, and effective medical service will depend largely on strong state organizations. A resolution was accordingly adopted calling on the component societies of the American Medical Association to activate committees that will work with and under the guidance of the Council.

Such a committee, although it had not yet been activated, had already been authorized by the Council of the Massachusetts Medical Society on October 2, 1946. This action was taken at that time as a logical procedure, with no emotional implications.

Further points were elaborated at the conference in April. In the event of such a national emergency as war with a foreign power, all the available medical personnel of military age should not be called up. Recent history has shown that too many stagnant pools of manpower result from this profligate policy. Another world war would be total to a degree never yet realized, and the ratio of one physician for each fifteen hundred of population, considered sufficient in World War II, would be inadequate for the expected civilian needs. A more flexible deployment of the medical profession to serve both our forces under arms and our population under fire would have to be arranged.

The regular branches of our armed forces should forget their old school ties and give the civilian components equal rank and consideration with their professional military personnel. In past wars it has been a rare honor for a civilian physician, however well equipped, to attain the rank of brigadier general. Furthermore, and this seems almost axiomatic, no emergency should be allowed to disrupt completely the continuity of medical progress and education. The possibility of a national future even after another war should not be entirely disregarded.

Certainly our minds must be kept open for the consideration of wholly new problems in this coldly scientific age. If war should come a new group of special weapons consisting of chemical agents, biologic products and releases of atomic energy with far reaching effects in both time and space will be available and might be employed. The medical profession will be of transcendent importance in

the event of such a disaster, and none of its value must be canceled out by outworn procedure or by antiquated customs of military regimentation. The chief obligation of civilized man, however, is to prevent, by the most forceful measures that can be undertaken, the catastrophe attendant on the opening of such a Pandora's box. In the contemplation of these weapons we are considering the zenith of military power. In a hypothetical fourth world war, as Einstein has mildly reminded us, man will perhaps revert to rocks as the only available missiles.

A combination of the wisest minds and the strongest hands must guide the future of the world. Their efforts must be directed toward the salvation and not the degradation of mankind. They must prepare for prevention, they must arm to keep the peace. The only fear permissible, as we have been told before, is that of fear itself.

Toynbee has shown that the civilization in control of its own destiny is that in which the creative minority remains actively in quest of moral and not of material gains. Our new, free, western civilization is still of that fiber. Its people are they that "shall mount up with wings as eagles, they shall run and not be weary, and they shall walk and not faint."

## VENEREAL-DISEASE CONTROL

A RECENT release from the Office of the Surgeon General reports a remarkable drop in the incidence of venereal disease during 1947.<sup>1</sup> For the Army as a whole, the decrease amounted to 40 per cent, for soldiers stationed in the United States, it was more than 50 per cent. This is an encouraging note in view of the trend toward increased rate in the civilian population as recently reported.<sup>2</sup> The Surgeon General credits this accomplishment to a new approach on the part of the Army, based on "an intelligent appeal to the higher moral sense of the individual," with "moral, spiritual, psychological, as well as objective factors." In this program the reasons for good conduct are stressed through group and individual education and conferences. Programs of activity and planned entertainment

help to maintain the interest of the soldier and to steer him away from sources of trouble when he is off duty. This approach has supplanted prior concepts, which emphasized the aspects of prevention, with the implication that the soldier was not remiss so long as his illicit relations did not result in infection. Training films used during the war have been replaced by new films reflecting the current trend, dramatizing "The rewards of good conduct as well as the effect of social diseases on an individual's future health and happiness."

Such a creditable accomplishment is certainly praiseworthy, and it is to be hoped that the rates of venereal disease among civilians will also be reduced. The statistical reports of the United States Public Health Service for the fiscal year 1947 show a rate 2 per cent less in the civilian population of the continental United States than had been predicted.<sup>3</sup> This is still a higher incidence than that of the preceding year. There is usually some degree of parallelism between military and civilian disease, but during periods of peace, the incidence of venereal disease in the general population is not likely to drop so much as the military rate.

A moral and spiritual approach is more likely to be effective in the absence of hostilities. The possibility of impending death that engenders a certain amount of reckless abandon and fatalism is bound to arise in the minds of troops in time of war. This factor complicates the moral aspect of the situation. Nevertheless, an education campaign in time of peace may well lay the foundation for better future success in the control of venereal disease.

## MASSACHUSETTS MEDICAL SOCIETY DEATH

ELLIS — Frederick W. Ellis, M.D., of Newton Centre, died on April 30. He was in his ninety-second year.

Dr. Ellis received his degree from Harvard Medical School in 1881. He was a fellow of the American Medical Association and the American Association for the Advancement of Science. He was the last surviving founding member of the American Physiological Society.

A son, Dr. Laurence B. Ellis, of Newton Centre, survives.

## A HUNDRED YEARS AGO

Within the circle of benevolent institutions, in this or other countries, there cannot be found a parallel to the one in the City of Boston organized expressly for poor, destitute, sick children. This is truly a charity which is not puffed up and which vaunteth not itself. It seeks no great names upon a circular, to give it importance, carries no contribution box into the church, makes no appeals to the pockets of the benevolently disposed, nor in any way seeks the applause of men. Quietly, without ostentation, without parade, but with a steady purpose, it feeds the hungry, clothes the naked, nurses the sick, and takes care of helpless little children. This is charity indeed, and of which our favored city, aye, and the world may be proud. — Notwithstanding the activity of the press in the United States, the question has been appropriately asked, what is the present state, and what are the future prospects, of the medical literature of this country? There is no dearth of authors. Originality of thought and boldness in execution are characteristics in the practice of American physicians and surgeons. Various institutions vie with each other in developing the resources of a science that investigates the laws of our being, and ameliorates the sufferings to which humanity is incident. New and striking exhibitions of mental effort, in all the various branches of medical study, are being made — and it is morally certain, that a few years will serve to bring out results that will redound to the advancing influence of the medical literature of the Union and place it on a foundation as firm and glorious as the government whose broad mantle covers and protects the whole. — By our exchanges we perceive that the various medical institutions of the country will be generally represented in the approaching meeting of the American Medical Association. The Counsellors of the Medical Society of Massachusetts have appointed fifty delegates. At that rate, throughout the country, the number of the whole will be great indeed. — A difficulty has existed in bringing within the embrace of the Massachusetts Medical Society all the well-qualified physicians of the Commonwealth. Some have not liked the payment, it is averred, of an annual tax of three dollars — particularly those who are located so far from the business center of the Society, Boston, as to make it expensive, and not always convenient, to attend, and such, believing that they could not receive an equivalent for their money, in becoming members, have wholly declined all connection. Others, who are excellent, stable-minded, staunch friends, and have exerted themselves to uphold the character of the Society, with veteran determination, have found themselves at times in embarrassment in not being able to consult with a practitioner who does not belong to the Society — a certain by-law

forbidding them to do so. All this has been discussed over and over again in the Council. It is confidently expected that alterations soon to be proposed will meet the cordial concurrence of all parts of the State, and that harmony, prosperity, influence and usefulness will follow their adoption. — Our colleagues in Buffalo, understanding that two Harvard students are at each other's throats for the honor of discovery of *Colloidal* — or what is termed in Buffalo the "new Boston notion" — hope that its parentage will be settled with less discussion and ink-shed than in the instance of the Ictheon. — Dr. Charles A. Greene of Millbury reports having seen last summer in Western New York, a young woman who had but three fecal discharges in nine years. She has but little physical strength. Her heart beats like an infant's, her respiration is peculiar, and so slight is the effort that it is hardly distinguished by a careful observer. There has been an attempt on the part of the physicians in her neighborhood to remove the underlying difficulty (whether it be a partial stricture of some part of the intestines, or a want of action in them, is unknown) but in vain. Oliver in his *Physiology*, makes mention of some persons having no discharge in one year, but no instance like the above has he ever found recorded. — Dr. T. J. W. Pray of Dover, New Hampshire reports the case of a Mr. Thompson, 35 years old, long subject to fits of intoxication. For five days previous to examination he had been in a beastly state of inebriation, and indeed it was found, upon inquiry, that he had drank in that time two gallons of "West India rum." At the expiration of the fifth day he wished medical aid. He seemed not to require any active medical treatment but rather the expectant plan, and he was depleted a very little for an experiment. The blood was forthwith drawn, and it was found destitute, in a measure, of its watery elements — alcohol having been substituted therefor. Immediately a lighted taper was applied to it, and it began to burn with a flame similar to that of alcohol. The fact that the blood did burn was substantiated by various respectable citizens of South Berwick who were eye-witnesses at the time the blood was drawn, and saw the experiment tried. The conflagration produced such an effect upon the patient that he refrained from his intemperate habits, and afterwards became a more sober man. — At the meeting of the American Medical Association in Baltimore, Dr. Holmes of Boston, of the Committee on Medical Literature, read a lengthy report, and very amusing withal. The report embraced a rather scathing review of American Medical Literature. The doctor was employed nearly two hours in reading it. It was laid upon the table. — The Annual Meeting of the Massachusetts Medical Society, which is the most interesting medical convention in New England occurs on the last Wednesday in May. At 10 o'clock A. M., the members assemble at the

Masonic Temple, Tremont Street, for the transaction of business. After the election of its Counsellors, and the delivery of a discourse by Dr L V Bell, they will dine together at Faneuil Hall, the renowned cradle of liberty — Extracted from the *Boston Medical and Surgical Journal*, April-May, 1848

## MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

### CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The June schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows

CLINIC	DATE	CLINIC CONSULTANT
Salem	June 7	Paul W Hugenberger
Haverhill	June 9	William T Green
Brockton	June 10	George W Van Gorder
Lowell	June 11	Albert H Brewster
Greenfield	June 14	Charles L Sturdevant
Springfield	June 15	Garry deN Hough, Jr
Pittsfield	June 16	Frank A Slowick
Worcester	June 18	John W O'Meara
Hyannis	June 24	Paul L Norton
Fall River	June 28	David S Grice

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

## MISCELLANY

### BOSTON LYING-IN HOSPITAL

Mr Richard D Mills has been appointed administrator by the trustees of the Boston Lying-in Hospital. Mr Mills, who served as a supply officer during the war, has been administrative assistant at the University Hospitals, Cleveland, and, since 1946, administrator of the Suburban General Hospital, Bellevue, Pittsburgh.

## CORRESPONDENCE

### SPONTANEOUS PNEUMOTHORAX

*To the Editor* The article by Dr Ralph M Myerson entitled "Spontaneous Pneumothorax," which appeared in the April 1 issue of the *Journal*, recalls a personal experience with this condition that may be of educational interest. While stationed with the United States Army in Bavaria, Germany, I was privileged to attend 2 cases and heard of a third case of spontaneous pneumothorax occurring in apparently healthy persons. All patients were young men — 2 American and 1 German. Each occurred while the patient was sking in the nearby Alps and was not, so far as could be determined, related to any falls or mishaps that accompany participation in this sport. Subsequent disposition of the 2 cases observed made follow-up studies impossible, but thorough examination at the time, aside from positive x-ray findings of the pneumothorax, failed to reveal any underlying or previous lung disease. An inquiry of a German physician indicated that such an occurrence is not too uncommon in the non-indigenous or inexperienced skier coming to that mountain area.

In view of the above experience two points arise for consideration. A rarely considered factor in the precipitation of spontaneous pneumothorax is described. Spontaneous pneumothorax in apparently healthy persons resulting from the decreased atmospheric pressure associated with airplane ascents and altitude-chamber studies is known to occur. That an inherent weakness in the pleura or the presence

of a superficial pleural bleb is a prerequisite is generally assumed in all cases of spontaneous idiopathic pneumothorax. In addition to the hyperventilation and increased depth of respiration attending a decrease in atmospheric pressure, sking superimposes the strain of strenuous exercise and motion of the arms and chest. This exertion may have been the only factor in the cases cited. But the fact that 2 of the cases and probably the third definitely occurred in apparently healthy persons under identical conditions implies that atmospheric pressure had a strong contributory effect. Secondly, it would be of interest to compare the incidence of spontaneous pneumothorax in healthy persons subjected to unaccustomed altitude variations similar to that in the cases cited above. Thus far, knowledge only extends to the influence of atmosphere under passive conditions. It may be necessary to make some revision in the statistics pertaining to this condition regarding both over all frequency and the particular locale studied.

Buffalo, New York

## BOOK REVIEWS

*Reading and Visual Fatigue* By Leonard Carmichael, Ph D, and Walter F Dcarbhorn, M D, Ph D. 8°, cloth, 483 pp, with 103 illustrations and 6 tables. Boston: Houghton Mifflin Company, 1947. \$5.00.

This book presents an excellent review of the literature on reading and visual fatigue, as well as the results of extensive new experimentation on these subjects conducted by the authors' associates. The Committee on Scientific Aids to Learning made financial grants to Harvard University and Tufts College to undertake the studies presented.

The first half of the book reviews in some detail the literature on visual fatigue and reading, the problem of illumination, blinking and the recording of eye movements. The second half describes experiments in which 40 high school and college students read for periods as long as six hours. During the reading continuous recordings were taken, providing an electroencephalogram, a horizontal electrooculogram, a vertical electrooculogram, an electrocardiogram and a record of page turns. The instrumentation appears to have been excellent, and the statistical analysis competent.

The results of the investigation support the modern view that "eye strain" is of central origin. The authors make the following statement:

The most important fact about reading for long periods as shown by the laborious recording and statistical techniques of these experiments is not a specific change in physiological mechanism. It is not a change in eye muscles, for example. Rather, the basic variable which seems to determine the presence or absence of changes during work done in long periods of time and which can be described as "fatigue" is a general characteristic of the subject's whole attitude toward his task.

The eye muscles are so much more powerful than is necessary for even prolonged reading that "the first index of fatigue seems to come in the alterations of the general attitudes and general feelings of the subject, not in a breakdown of the sensory-neuromuscular mechanism which actually performs the task."

The book should be of particular interest to all who are concerned with visual education.

*Stereoscopic Atlas of Neuroanatomy* By H S Rubenstein, M D, Ph D, and C L Davis, M D. 4°, boxed, 19 pp, and 43 stereoscopic plates. New York: Grune and Stratton, 1947. \$10.00.

This atlas was designed primarily for the use of students and physicians taking a refresher course in brain anatomy. It consists of forty-three single plates, and a small pamphlet, comprising a dissection manual and an index to the plates. Each plate has a lettered localization diagram in addition to the photographic reproduction of brain structure. The artwork is good, and the atlas should prove valuable to interested persons.

Dr. Edward J. Ferrarone announces the opening of his office at 289 State Street, Springfield for the practice of orthopedic surgery

## NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, June 3, at 7:15 p.m. in the classroom of the Nurses' Residence. The subject "Obstetric Cases" will be discussed by Dr. Marjorie Woodman. Dr. R. Adelaide Draper will be chairman

## NEW ENGLAND PEDIATRIC SOCIETY

The spring meeting of the New England Pediatric Society will be held in New Haven, Connecticut, on Wednesday, June 9

### PROGRAM

At New Haven Hospital (789 Howard Avenue)

- 12 m. to 1 p.m. Pediatric Conference
- 1 to 2 p.m. Luncheon
- 2 to 4:30 p.m. Scientific Program

At New Haven Medical Association (364 Whitney Avenue)

- 5 to 6 p.m. Social Hour
- 6 p.m. Dinner
- 7 p.m. Multiple Birth in Colonial Times. Dr. Ernest J. Caulfield, of Hartford, Connecticut.

## SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JUNE 3

### THURSDAY JUNE 3

- 7:15 p.m. Monthly Clinical Conference and Staff Meeting. New England Hospital for Women and Children

### FRIDAY JUNE 4

- \*10:00 a.m.-12:00 m. Medical Staff Round. Peter Bent Brigham Hospital

### TUESDAY JUNE 8

- \*12:15-1:15 p.m. Clinico-orthopedic Conference. Peter Bent Brigham Hospital
- \*1:30-2:30 p.m. Pediatric Rounds. Burroughs Memorial Hospital for Children. Massachusetts General Hospital

### WEDNESDAY JUNE 9

- 12:00 m. New England Pediatric Society. New Haven Hospital and New Haven Medical Association Headquarters.
- \*12:00 m. Grand Rounds and Clinicopathological Conference (Children's Hospital). Amphitheater. Peter Bent Brigham Hospital
- \*2:00-3:00 p.m. Combined Clinic by the Medical, Surgical and Orthopedic Services. Amphitheater. Children's Hospital

\*Open to the medical profession

## HARVARD MEDICAL SCHOOL

Courses for Graduates

MODERN TREATMENT OF FRACTURES  
AND OTHER TRAUMATIC CONDITIONS

at the

MASSACHUSETTS GENERAL HOSPITAL

September 20 to 30, 1948

This course will deal primarily with the treatment of fractures, but the management of many other traumatic conditions will be presented — namely the physiology of bone repair, soft-tissue injuries, surgical shock, bone metabolism, burns, hand surgery, plastic surgery, vascular injuries, chest injuries, trauma in the central nervous system, bone tumors, anesthesia in traumatic conditions, the use and misuse of x-rays in the handling of fractures and physical therapy and rehabilitation

Tuition — \$150

## TEMPORARY REMISSIONS IN ACUTE LEUKEMIA IN CHILDREN PRODUCED BY FOLIC ACID ANTAGONIST, 4-AMINOPTEROYL-GLUTAMIC ACID (AMINOPTERIN)\*

SIDNEY FARBER, M.D.,† LOUIS K. DIAMOND, M.D.,‡ ROBERT D. MERCER, M.D.,§

ROBERT F. SYLVESTER, JR., M.D.,¶ AND JAMES A. WOLFF, M.D. ||

BOSTON

IT IS the purpose of this paper to record the results of clinical and hematologic studies on 5 children with acute leukemia treated by the intramuscular injection of a synthetic compound, 4-aminopteroylglutamic acid (aminopterin). This substance is an antagonist to folic acid regarding the growth of *Streptococcus faecalis* R.

The occurrence of what he interpreted as an "acceleration phenomenon" in the leukemic process as seen in the marrow and viscera of children with acute leukemia treated by the injection of folic acid conjugates<sup>1</sup>—pteroyltriglutamic acid (teropterin) and pteroyldiglutamic acid (diapterin)—and an experience gained from studies on folic acid deficiency suggested to Farber that folic acid antagonists might be of value in the treatment of patients with acute leukemia.<sup>2</sup> Post-mortem studies of leukemic infiltrates of the bone marrow and viscera in patients treated with folic acid conjugates were regarded by Farber as evidences of an acceleration of the leukemic processes to a degree not encountered in his experience with some 200 post-mortem examinations on children with acute leukemia not so treated. It appeared worth while, therefore, to ascertain if this acceleration phenomenon could be employed to advantage either by radiation or nitrogen mustard therapy after pre-treatment with folic acid conjugates or by the administration of antagonists to folic acid.<sup>3</sup> A series of folic acid antagonists was made available by Dr. Y. Subbarow and his colleagues.<sup>3-5</sup>

The objective data sufficient to justify research in the direction of antagonists to folic acid in the treat-

ment of leukemia were obtained from studies on a four-year-old girl with a rapidly progressing acute myelogenous leukemia. Treatment from February 17 to March 24, 1947, with pteroyldiglutamic acid (diapterin), in a dosage of 100 to 300 mg intramuscularly daily, had no effect upon the hematologic picture. The patient appeared to be moribund. A second bone-marrow biopsy on March 25 verified the diagnosis of myelogenous leukemia. Pteroylaspartic acid, the first antagonist to folic acid to be employed in our studies, was given intramuscularly from March 28 to April 4 in amounts of 40 mg daily without altering the clinical course. Post-mortem examination on April 4 revealed a markedly hypoplastic bone marrow, with a few immature cells. A change of this magnitude in such a short time has not been encountered in the marrow of leukemic children in our experience.

This observation was followed by clinical, laboratory, and post-mortem studies\*\* on a group of 14 children with acute leukemia treated with pteroylaspartic acid and on 7 treated with methylpterotic acid. The details of these observations will be reported separately.

Sufficient encouragement was obtained from these observations to justify further studies on the effect of more powerful antagonists to folic acid on the course of acute leukemia in children. Since November, 1947, when a sufficiently pure substance became available, to the time of this writing (April 15, 1948) we have made studies on 16 children with acute leukemia to whom the most powerful folic acid antagonist we have yet encountered, 4-aminopteroylglutamic acid (aminopterin††) was administered by intramuscular injection. Many of these children were moribund at the onset of therapy. Of 16 infants and children with acute leukemia treated with aminopterin 10 showed clinical, hematologic and pathologic evidences of improvement of important

nature of three months' duration at the time of this report. Six patients did not respond well, 4 of these are now dead, and 2 were unimproved. This paper presents detailed clinical, hematologic and bone-marrow studies in 5 children selected from these 10 who showed evidences of important improvement—the course in the other cases was essentially similar. The patients are selected for the purpose of illustrating some of the problems concerned with the use of aminopterin and because they demonstrate the best results that we have

FIGURE 1 Course of Leukemia in Case 1

observed. The toxic effects are stressed in these histories, and the temporary nature of the remissions is emphasized.

### CASE REPORTS

**CASE 1** W G, a 7 1/2-year-old boy, entered the hospital for the first time on April 9, 1947, with complaints of joint pain and fever. He had been generally well until 7 weeks before admission, when pain developed in the right knee. There were no associated physical abnormalities, and the pain promptly subsided. Five days later pain recurred in the right elbow, and a low-grade fever was noted. Migratory arthralgia and fever continued until admission.

Physical examination revealed only moderate pallor and slight enlargement of the liver and spleen. The boy appeared well developed and nourished and not particularly ill.

Examination of the blood disclosed a red-cell count of 3,670,000, with a hemoglobin of 10.6 gm, and a white-cell count of 56,000, with 73 per cent blast forms. The platelet count was normal. A bone-marrow biopsy revealed leukemia.

The patient was treated with pteroylglutamic acid beginning on April 16 in doses of 20 to 60 mg daily while in the hospital, in a convalescent home, where he remained until May 20, and at home, where the injections were given by the family physician. During that time he was active and fairly well, although the white-cell count remained high and the red-cell count and hemoglobin fell slowly.

On July 1 diopterin, in a dosage of 200 mg by mouth daily, was begun. This therapy was continued for about 1 month, during which the patient steadily became more ill. The liver and spleen enlarged, and he became very anemic. The blast forms in the peripheral blood rose to 94 per cent. Joint pain and fever recurred, and by August 13 he was critically ill, with a temperature reaching 106°F. He was readmitted to

the hospital and received several transfusions. Pteroylglutamic acid and methylpterol, in doses of 40 mg each, were given intramuscularly daily. The patient was discharged after about 2 weeks, and pteroylglutamic acid and methylpterol, in doses of 20 mg each, were continued in the Tumor Therapy Office. A period of remission ensued, during which the red-cell count and platelets returned to normal levels, the liver and spleen receded in size and the nutrition improved remarkably. He returned to school part time in October and was in quite good condition. The white-cell count had risen to high levels, however, and in November general deterioration began. The liver and spleen enlarged, and he became so anemic that transfusion was necessary by November 24. Only temporary benefit resulted and transfusions were required at about 3-week intervals.

Aminopterin was started on December 16 and given daily, in doses of 0.5 mg intramuscularly, for six doses. By December 30 the white-cell count had fallen from 60,000 to 19,000. There was moderate improvement in activity and appetite. Thereafter unfavorable weather made daily visits to the clinic impossible, and 1 mg of aminopterin was given approximately three times weekly for about a month. During that time there was no striking clinical or hematologic improvement, although the patient was not seriously ill.

On February 3 daily injections of 1 mg of aminopterin were begun. A bone-marrow biopsy and aspiration revealed 85 per cent blast forms, no megakaryocytes and no erythropoiesis. After 10 days of regular therapy the white-cell count had fallen from 78,000 to 5000, but severe stomatitis made cessation of therapy imperative. Within a week without therapy, the stomatitis had healed completely, and the patient had developed a ravenous appetite. The nutrition gradually improved. By February 21 the liver was no longer palpable, and only the tip of the spleen could be felt. Bone-marrow aspiration and biopsy revealed a slight decrease in blast forms and slight erythropoietic activity. The platelets reached normal levels about 1 month after this course of daily therapy. On March 1 the white-cell count began to rise in spite of daily administration of 0.25 mg of aminopterin, and by March 6 was 75,000. The spleen again enlarged. The dosage of aminopterin was raised to 1 mg on March 8, and after about 10 days the white-cell count had fallen to 12,000. Slight stomatitis again appeared, and the dosage of aminopterin was reduced to 0.5 mg daily, with 1 unit of crude liver extract weekly. The white-cell count has remained at a high-normal level, and the spleen is again slowly receding. The stomatitis is still present but is not progressing and does not interfere with ability to eat.

The leukemia in this case progressed slowly during treatment with pteroylglutamic acid and methylpterol, but during a course of diopterin became rapidly worse (Fig 1). The liver and spleen enlarged, severe anemia developed, and the blast forms in the peripheral blood rose above 90 per cent. The patient appeared critically ill, with a maximum temperature of 106°F. Transfusions and therapy with these two folic acid antagonists were followed by a marked but temporary remission. Irregular therapy with aminopterin has been of no benefit, but on two occasions daily injections have produced good clinical and hematologic remissions. On both occasions, stomatitis has interfered with optimal use of the drug. At the time of writing the patient is in excellent physical condition.

**CASE 2** R P, a 6 1/2-year-old boy, was admitted to the hospital on March 4, 1948, with the chief complaint of increasing pallor. His growth, development and general health had been excellent until about 3 weeks before admission, when tonsillitis had developed. This had subsided promptly, but the patient had become lethargic, and increasing pallor was noted. About 10 days before admission his parents began to notice that he bruised easily.

Physical examination disclosed a well developed and fairly well nourished boy who was very pale and lethargic. Many small ecchymoses were noted over the extremities. The liver edge extended 4 cm. below the costal margin, and the tip of the spleen could be felt at the costal margin. There was slight generalized lymphadenopathy.

Examination of the blood revealed a red-cell count of 1,880,000 with a hemoglobin of 5.65 gm and platelets of 46,000 and a white-cell count of 4200, with 20 per cent immature or blast forms. A sternal marrow aspiration revealed 75 per cent blast forms. No megakaryocytes were seen.

Shortly after admission the patient developed a spiking temperature up to 104 or 105°F daily, and rapidly became more lethargic. Blood cultures revealed no growth. Frequent transfusions raised the red-cell count and hemoglobin to normal levels, but there was an unfavorable clinical response. The white-cell count fell to 1500. He appeared critically ill. On the 7th hospital day penicillin was started, and the temperature decreased although it continued to reach 101 to 102°F daily.

On the 8th hospital day, aminopterin (1 mg) and crude liver extract (1 unit) were given intramuscularly. The white cell count was 1500. This medication was continued daily and the patient rapidly became more alert and active. The white-cell count remained near 2000. He was discharged moderately improved on March 15. After discharge he was seen 6 times weekly in the Tumor Therapy Clinic and 1 mg of aminopterin and 1 unit of crude liver extract were given at each visit. Rapid improvement in appetite and activity continued. A second sternal marrow biopsy and aspiration after one week of therapy revealed a 25 per cent decrease in blast forms and an increase in more mature leukocytes and megakaryocytes. By March 25 the white-cell count had reached 5000, with 34 per cent neutrophils, 63 per cent lymphocytes and 2 per cent blast forms. His activity and appetite were normal and easy bruising was no longer a complaint. At about that time he developed minor

returned to normal and he is in school part time. The red-cell count and hemoglobin are still high, and the white-cell count is within normal limits. Immature cells or blast forms have disappeared from the peripheral blood, and the bone marrow shows a moderate shift toward maturity of leukocytes, with an increase of erythrocyte precursors and megakaryocytes. The course is demonstrated in Figure 2.

**CASE 3** G J, a 3 8/12 year-old boy was admitted to the hospital on November 2, 1947—5 days after the onset of an acute illness with sore throat and fever.

The past history and developmental history were not remarkable.

Physical examination disclosed a critically ill patient with an acute follicular tonsillitis and enlarged tender cer-

FIGURE 2 Course of Leukemia in Case 2

lesions of the oral mucosa. The dosage of aminopterin was reduced to 0.5 mg and the liver extract was given once weekly. Steady improvement has continued. The liver and spleen are no longer palpable. The patient is active in outdoor games and his endurance is good. On March 31 he returned to school where his teacher noted marked improvement in his appearance and interest. Sternal marrow aspiration on April 1 revealed a slight further reduction in blast forms, a moderate increase in megakaryocytes and a marked increase in erythropoiesis. He continues on daily injections of 0.5 mg of aminopterin with liver extract once weekly.

This patient had rapid progression of leukemia until one month after the onset, when he appeared critically ill. After three weeks of daily aminopterin therapy his activity and appearance have

FIGURE 3 Course of Leukemia in Case 3

vical lymph nodes. There was no generalized adenopathy and no hepatomegaly or splenomegaly. A blood culture was positive for beta hemolytic streptococcus.

Examination of the peripheral blood showed a red-cell count of 1,900,000, a white-cell count of 480 and a platelet count of 123,000. Bone-marrow aspiration showed 16.4 per cent blast forms, 3.2 per cent mature polymorphonuclear leukocytes, 76.2 per cent lymphocytes and 1.6 per cent erythroid elements. On the basis of the bone marrow aspiration a diagnosis of leukemia was made. The bacteremia was treated with penicillin and streptomycin.

After recovery from the infection the patient went into a complete clinical and hematologic remission for about 2 months. The course is demonstrated in Figure 3. At that time bilateral acute otitis media developed. Two weeks later the total nucleated count of the sternal bone marrow was 910,000 (normal 200,000 to 250,000) with 96 per cent blast forms (Fig. 4A). By February 26, 1948 the white-cell count was 17,250, with 80 per cent blast forms the spleen extended to the umbilicus, petechiae began to appear, and it was obvious that the child was entering a rapidly progressive phase of the leukemia.

He was readmitted to the hospital on March 6. He appeared chronically ill with pallor, petechiae, moderate generalized lymphadenopathy and marked hepatomegaly and splenomegaly. The white-cell count, which was 30,400 with 86 per cent blast forms on admission fell rapidly to 900 by March 12, and the patient appeared moribund. Blood cultures were negative.

Aminopterin was started on March 13 in doses of 0.5 mg and given for 5 consecutive days. Crude liver extract, in a dosage of 1 unit daily, was given in the same syringe. At

the end of that time there was no noticeable clinical improvement, but the white-cell count, which was still 900, contained only 5 per cent blast forms. A sternal-marrow smear made at the end of this short period of therapy and compared to one just before therapy was started showed a shift to the right, with some reduction in blast forms and an increase in more mature forms of granulocytes, as well as a slight increase in erythroid elements. Aminopterin was discontinued until it became apparent that the leukopenia was not increasing.

After 4 days without treatment 0.5 mg of aminopterin daily, with 1 unit of crude liver extract, was given once more. The white-cell count increased gradually, and blast forms

**CASE 4** C C, a 2 1/12-year-old girl, was admitted to the hospital on August 22, 1947. Six weeks previously her father had noticed lumps about the head and neck. Two weeks previously her family physician had made a diagnosis of leukemia on the basis of a peripheral blood smear.

Physical examination revealed a pale girl, with ecchymotic areas over the lower extremities. There was marked generalized adenopathy, particularly about the parotid region, and the liver edge and tip of the spleen extended down to the iliac crests.

Examination of the blood disclosed a white-cell count of 75,000, with 80 per cent blast forms. The platelet count

FIGURE 4 Photomicrographs of the Sternal Bone Marrow in Case 3, Showing Giemsa-Stained Section on January 29, (A) and April 3 (B), 1948 ( $\times 1000$ )

Note that the microscopical field is composed mainly of blast forms characteristic of leukemia (cell type undetermined) in the early section (A) and that a marked shift to mature cell forms, particularly of the polymorphonuclear series, with no leukemic cells, had occurred on the later examination (B)

disappeared from the peripheral blood. The child began to show clinical improvement, his appetite became better, and the liver and spleen became scarcely palpable. The petechiae and generalized adenopathy disappeared.

At the present writing there is a partial contracture of the left leg, probably resulting from leukemic infiltrations about the knee joint and in the gastrocnemius muscle. The tip of the spleen is still palpable. Otherwise the child is normal on physical examination. The white-cell count is 6700, with a normal differential. The platelet count is 152,000. Aspiration of the sternal marrow on March 29 revealed 8 per cent blast forms, with an increase in more mature granulocytes, erythrocyte precursors and megakaryocytes (Fig 4B).

This child with acute leukemia had a remission of about two months' duration after a bacteremia. At the time aminopterin was started he was in a rapidly progressive phase of the leukemia and appeared moribund. After five days of therapy there was marked improvement in the peripheral-blood and sternal-marrow picture. He has continued to demonstrate rapid and remarkable clinical improvement. Eighteen days after therapy was started the sternal-marrow aspiration showed only a slight shift toward immaturity of the myeloid elements and a moderate reduction of lymphocytes and erythroid elements. The peripheral blood at present shows slight thrombocytopenia, with a white-cell count of 8000 and a differential count that is essentially normal except for a large number of band forms.

was 54,000. The patient was discharged and given x-ray therapy to the parotid region in the outpatient department. A total of 600 r was given from September 4 to September 8. The white-cell count, which was 94,000 on September 4, had dropped to 5000 by September 11.

The patient was readmitted on September 27. She was much worse, with a poor appetite, marked pallor and massive adenopathy. The white-cell count was 1000, with 30 per cent blast forms. Several transfusions before discharge produced only slight improvement.

The third admission, on November 6, followed a generalized convulsion. The patient was comatose, with a temperature of 103.6°F.

Physical examination was essentially unchanged except that the kidneys were definitely enlarged and easily palpable. There was no positive evidence of infection. A transfusion and penicillin were given, and the patient was discharged in fair condition.

The fourth and last admission was on December 2, when there was a temperature of 105°F. There was a severe stomatitis and pharyngitis, with extensive exudation. The left ear was inflamed but not suppurating. Bronchopneumonia was present on the left. A lumbar puncture showed evidence of subarachnoid hemorrhage. A blood culture was positive for *Staphylococcus aureus*, coagulase positive.

For the first 6 hospital days the patient ran a septic temperature ranging between 105 and 103°F. She was given penicillin and sulfadiazine, as well as repeated blood transfusions, throughout the hospital stay. At this admission she was seen for the first time by the Tumor Clinic and received 20 mg of teroplerin per day for eighteen doses, from December 3 through December 20.

On several occasions the patient appeared moribund but on about the 7th hospital day she began to improve and continued to improve until the time of her discharge. The white-cell count, which had dropped to 650 on the 4th hospital day, rose to 6400 on the day before discharge. The differential count included 68 per cent neutrophils, 24 per

cent lymphocytes and 8 per cent monocytes. There were no blast forms.

After this severe infection there was a remission in the clinical and hematologic condition. During that time the patient was given an occasional dose of rotopernin to a total of 140 mg. By January 13 small lymph nodes over the scalp, parotid and cervical regions had begun to develop. These rapidly increased, and by January 19 there was massive generalized adenopathy. The peripheral blood and bone marrow continued at values approaching normal. There were only occasional to 5 per cent blast forms in the peripheral blood, with a normal total white-cell count, and 84 per cent blast forms in the bone marrow with a slight depression of mature forms and a moderate depression of erythroid forms. On January 20 aminopterin was started in doses of 1 mg daily with 20 mg of rotopernin daily. This was given on twenty six clinic visits from January 20 to February 21. Four days after treatment had been started there was a marked decrease in the size of all the lymph nodes. In 2 weeks the patient was normal on physical examination. Her appetite became very good, her disposition happy, and she began to play and run about like a normal child. Her parents stated that she was better than she had been before she became sick for the first time. Since treatment was stopped she has continued to do well. She has been without treatment since February 21 and at present is completely normal on physical examination. The total white-cell count is 9000, with an occasional blast form. The platelet count is 256,000, the red-cell count 4,600,000 and the hemoglobin 14.8 gm.

This child is known to have had acute leukemia since early in August, 1947. Her course was rapidly and progressively downhill until December, when she had a fulminating generalized infection with bacteremia. After this she had clinical and hematologic evidence of remission. In the middle of January a relapse was taking place, as evidenced by massive generalized adenopathy although the blood and bone-marrow picture remained the same. After aminopterin therapy the adenopathy disappeared. The patient has remained clinically well for forty-three days without treatment and shows an essentially normal hematologic picture at the time of writing. The course is shown in Figure 5. At the end of forty-seven days without treatment a few nodules appeared beneath the scalp and in the subcutaneous tissue over the face. It is probable that these represented leukemic deposits, although at the time of their appearance the peripheral blood was still essentially normal. Because of this finding the treatment has been reinstituted.

**CASE 5.** R. S., a 2 1/2-year-old boy, was admitted to the hospital on August 26, 1947, with the chief complaint of increasing pallor. He was one of identical twins and his birth growth and development, and general health had been unremarkable. About 10 days before admission he had developed a low-grade fever soon followed by increasing pallor, lethargy, anorexia and intermittent vomiting.

Physical examination showed a fairly well developed and well nourished and only moderately ill boy. He was very pale. There was generalized enlargement of the lymph nodes and moderate hepatomegaly and splenomegaly. X-ray study showed marked infiltration of the long bones. The hemoglobin was 5.5 gm., and the white cell count 12,400, with 41 per cent immature or blast forms.

During 2 weeks in the hospital the patient received transfusion, which restored the hemoglobin to normal levels. After discharge he was seen in the Tumor Therapy Clinic daily except Sunday and on each visit received 20 pteroylaspatic acid intramuscularly. He has been on this regime for about 2 months, during which the

progressed slowly but steadily. He became less alert and less active. He developed a limp. There was gradual weight loss, and the liver and spleen continued to enlarge. The leukocytes remained at normal levels but the percentage of blast forms increased. The red cell count and hemoglobin slowly fell, until on November 6 it was necessary to admit him to the hospital for transfusion. At that time a small pathologic fracture was noted in the left tibia. After discharge he was seen in the Tumor Therapy Office three times weekly and on each visit received 40 mg of pteroylaspatic acid intramuscularly. Late in November there was a definite acceleration in the progress of the disease. The white-cell count began to rise and the platelets fell. The patient began to bruise easily and had occasional slight oozing from the gums. He developed moderate exophthalmos. He refused to walk. Hospitalization was necessary twice in the

FIGURE 5 Course of Leukemia in Case 4

early weeks of December for treatment of arthritis and upper respiratory infection. Stereal marrow aspiration at that time revealed 40 per cent blast forms and little erythropoiesis. By the end of December the patient appeared moribund. He had marked generalized adenopathy, marked hepatomegaly and a spleen whose tip extended into the pelvis. There was moderate dyspnea and stridor, pallor, marked wasting and exophthalmos. There were many ecchymoses, and oozing occurred at the gingival margins.

Aminopterin therapy was begun on December 28. On each of 3 successive days the patient received 10 mg of the drug intramuscularly. During that time the white-cell count began to fall rapidly from the pretreatment level of 60,000. By December 31 the count was 9000 and respiratory difficulty was even more marked. He was admitted to the hospital. Aminopterin was discontinued and a transfusion was given. He was discharged on January 3, 1948, slightly improved but with the white-cell count only 2700. After discharge he was again followed in the Tumor Therapy Clinic. By January 13 marked clinical improvement had become apparent. The patient was walking for the first time in 2 months, and respiratory difficulty had disappeared. His appetite was ravenous. There was no more bleeding. "His clothes became loose about the abdomen." On January 27 the white-cell count reached 5000, and 0.5 mg of aminopterin was started and given three times weekly. Gradual improvement continued but a white-cell count of about 3000 persisted. In the middle of February, rotopernin in 10-mg amounts was given with each dose of aminopterin for five doses. Early in March a rise in the hemoglobin and red cell count began. Since then folic acid for a time and lately crude liver extract have been used in conjunction with aminopterin. There had been steady clinical and hematologic improvement so that at the time of writing activity, alertness and nutrition are equal to or better than those of the well tw. The liver and spleen have decreased in size, so that they are barely palpable beneath the costal margins. The red-cell and

count, differential counts and platelets are within normal limits. The sternal marrow, examined by biopsy, is normally cellular, and the differential count is normal. Erythropoiesis is active, and megakaryocytes are present in normal number.

This boy exhibited slow but regular progression of leukemia from the time of diagnosis in August, 1947, until December, when he became rapidly worse. By January, 1948, he appeared moribund. After three daily doses of 1 mg. each of aminopterin there was a rapid fall in the white-cell count, followed in about ten days by remarkable clinical improvement. On maintenance therapy there has been continued improvement until at present the

FIGURE 6 Course of Leukemia in Case 5

patient is clinically well and all the laboratory data are within normal limits. The course is demonstrated in Figure 6.

DISCUSSION

Clinical, hematologic and histologic details are given concerning 5 children with acute undifferentiated leukemia treated with aminopterin. These patients were selected from a group of 10 who responded favorably to the use of this substance. The 10 were members of a group of 16 children with acute leukemia—6 did not respond well, and of these, 4 are now dead. The observations on these patients show that the aminopterin has a marked effect upon the leukemic bone marrow and upon the immature cells in the peripheral blood, and judging from the disappearance of enlargement of the spleen, liver and lymph nodes, when those organs were enlarged, very probably on leukemic deposits in the viscera as well.

Under treatment with aminopterin the white-cell count tended to return to a normal level. This occurred in patients in whom the count was initially high and also in those in whom there was marked leukopenia at the onset of the therapy. The percentage of immature cells fell, and the blast forms decreased markedly and in some cases disappeared from the peripheral blood. The relative percentages of mature leukocytes tended to approach normal values in the peripheral blood. The peripheral-blood changes included improvement approaching the normal in the value of hemoglobin, red-cell count and platelets. Studies of the bone marrow showed changes that varied from a decrease in number to a disappearance of the leukemic cells and variation from hypoplasia to almost normal pattern. Toxic effects included stomatitis, with early ulceration. In an attempt to prevent this complication crude liver extract was employed, as were folic acid and folic acid conjugates.

This report describes only temporary remissions produced by the injection of aminopterin in children with acute leukemia. It is impossible to state whether the substance will be of value for a longer period than that covered by these studies. The toxic effects may make continued use of the drug impossible. One patient (Case 4) had been without treatment for forty-three days after having had a satisfactory remission. During this time the peripheral blood and the sternal bone marrow became essentially normal. At the end of forty-seven days without treatment a few nodules appeared beneath the scalp and in the subcutaneous tissue over the face. It is probable that these represent leukemic deposits, although at the time of their appearance the peripheral blood was still essentially normal. Because of this finding the treatment has been reinstituted. After ten days of aminopterin treatment, the nodules have disappeared once more.

These studies justify a search for other antagonists to folic acid that are less toxic than aminopterin and may be even more powerful.

SUMMARY

Clinical, hematologic and histologic details of 5 patients with acute leukemia treated with aminopterin, selected from a group of 16 patients so treated, form the basis of this paper. It is again emphasized that these remissions are temporary in character and that the substance is toxic and may be productive of even greater disturbances than have been encountered so far in our studies. No evidence has been mentioned in this report that would jus-

tify the suggestion of the term "cure" of acute leukemia in children. A promising direction for further research concerning the nature and treatment of acute leukemia in children appears to have been established by the observations reported.

Acknowledgment is made to Dr. I. Subbarow and his colleagues in the Research Division of the Lederle Laboratories (American Cyanamid Company) and their associates of the Calco Chemical Division, who are responsible for the chemical research that made possible these studies on children.

## SARCOMA OF THE UTERUS\*

### A Report of Eighteen Cases

THOMAS PERRY, JR., M.D.†

PROVIDENCE, RHODE ISLAND

ALTHOUGH sarcomas of the uterus are rare in comparison with the carcinomas of that organ, certain features of their histogenesis, pathology and clinical course make them an interesting group. Two recent cases, a sarcoma botroides and a late metastasizing leiomyosarcoma, prompted a review of the 18 cases of sarcoma of the uterus seen at the Rhode Island Hospital in the past eighteen years. Special attention has been paid to the pathology of these cases with a view to determining their probable origins and the relation of cytologic characteristics to prognosis. Observations have also been made on the clinical characteristics of the disease, with particular reference to radiation therapy. Four cases are of sufficient interest to be reported in some detail.

A brief review of the literature serves to orient one concerning the types of tumors encountered and their incidence. In 1863 Virchow<sup>1</sup> pointed out that sarcomas may arise both in the smooth muscle of the uterus and in the stromal cells of its mucosa. Geisler<sup>2</sup> noted that sarcoma constituted 2 per cent of uterine cancers, Novak and Anderson<sup>3</sup> found 4.5 per cent, and others a similar or slightly higher incidence. Piquand,<sup>4</sup> in a collective study, reported 68 cases of sarcoma of the cervix as compared with 325 of the body. Others found a much lower incidence of tumors in the cervix (Gessner<sup>5</sup> and Meyer<sup>6</sup>).

Nearly all authors report a preponderance of leiomyosarcomas over other forms of uterine sarcomas. Leiomyosarcomas may be of a very low grade of malignancy, some being classified as recurrent fibroids. Others are extremely anaplastic, widespread and rapidly fatal. Various gradations between the two extremes are to be found. Grossly, the tumors may be nodular or may grow diffusely. Polypoid projections into the endometrial cavity are not uncommon.

Stromal or mucosal cell cancers of the endometrium make up the other large group of uterine sarcomas. These are usually characterized by round cells rather than the spindle cells found in typical leiomyosarcoma. The group may be enlarged to include the various types of mixed tumors, which, in spite of their pleomorphism, presumably arise from stromal cells or their anlage. A rather confusing nomenclature has arisen for them, but, for the purposes of this paper, the following terminology is used. Mixed mesodermal tumors are those containing more than one type of tissue of mesodermal origin. Cartilage, striated muscle and myxomatous elements are most frequently encountered, but many other types of tissue have been noted. The term carcinosarcoma is used to designate tumors containing elements of connective-tissue origin and epithelium. It cannot be argued that the presence of epithelial cells sets the carcinosarcomas apart from other mixed tumors, but the term is descriptive and gives some indication of cell structure. From a careful study of the histology of the cases reported in this paper it seems likely that a large proportion of stromal-cell tumors show a mixed histology. Multiple microscopical sections may reveal small islands of cartilage or bizarre epithelial elements that are overlooked in routine observation. Thus, it was possible to reclassify several of the tumors reported below.

Two other types of rare sarcoma should be mentioned: hemangiosarcoma and sarcoma botroides. The latter is the grapelike tumor most often found in the cervical portion of infants, but also seen in adults. It presents a mixed histology, which includes epithelium, myxomatous tissue, striated muscle and, at times, a variety of other elements. This tumor is extremely malignant.

Any series of these tumors includes some that are too anaplastic to be classified. Certain others are characterized only by round cells and large num-

bers of giant cells (Fig 1 and 2) Inasmuch as both leiomyosarcomas and stromal-cell tumors tend to form giant cells these tumors cannot always be ac-

can be distinguished It will be seen, therefore, that a mullerian-duct cell can give rise to smooth muscle, endometrial stroma or epithelium This fact may well account for the pleomorphism of some of the tumors encountered

From 1929 through February, 1947, 18 patients with sarcomas of the uterus have been treated at

FIGURE 1 *Advancing Edge of a Predominantly Giant-Cell Tumor (Case 16)*

FIGURE 2 *A Few Areas Suggesting Stromal-Cell Origin from the Same Tumor As That Shown in Figure 1*

curately pigeonholed Novak and Anderson<sup>3</sup> point out that the giant cells are often evidence of degeneration of the tumor and that a diagnosis can frequently be made by a careful search for areas with few giant cells

The varied histology of the mixed types of tumors calls for some consideration of their histogenesis It

the Rhode Island Hospital These can be classified as follows leiomyosarcoma, 7 cases, mixed mesodermal sarcoma, 4 cases, carcinosarcoma, 3 cases, giant-cell (probably stromal-cell) sarcoma, 2 cases,

TABLE 1 *Results of Treatment in Patients with Leiomyosarcoma*

CASE No	AGE OF PATIENT	TREATMENT	PERIOD OF SURVIVAL	REMARKS
	yr		mo	
1	90	Panhysterectomy and bilateral salpingo-oophorectomy	3	Gross tumor not completely removed, patient died of leiomyosarcoma
2	65	Panhysterectomy and bilateral salpingo-oophorectomy	5	No recurrence of tumor patient died of chronic myocarditis
3	48	Panhysterectomy and bilateral salpingo-oophorectomy	66	Recurrence after 4½ years, patient living
4*	54	Panhysterectomy and bilateral salpingo-oophorectomy 2400 r postoperatively	8	Gross tumor not completely removed, patient died of leiomyosarcoma
5*	20	Supracervical hysterectomy	48	No recurrence, patient living
6	53	Supracervical hysterectomy and unilateral salpingo-oophorectomy, 2150 r postoperatively	6	Gross tumor not completely removed, patient died of leiomyosarcoma
7*	43	Panhysterectomy and bilateral salpingo-oophorectomy	12	No recurrence, patient living

\*These patients showed few mitoses, indicating good prognosis

will be recalled that both myometrial and endometrial elements of the uterus are derived from the müllerian ducts, which, in turn, are outpouchings of the wolffian ducts, the last being of mesodermal origin In the uterus of the 80-mm embryo (Pren-

tiss and Arey<sup>7</sup>) myometrial and endometrial layers stromal-cell sarcoma, 1 case, and sarcoma botroides, 1 case

The results of treatment in the patients with leiomyosarcoma have not been encouraging (Table 1) In 3 cases gross tumor had to be left behind at the time of operation, and all these patients were

dead within eight months. In the other cases, viewed as possible cures at the time of operation, 1 patient died in five months without evidence of recurrence, 1 developed a distant metastasis after four and a half years, and 2 are living and well one and four years, respectively, after operation.

Panhysterectomy with bilateral salpingo-oophorectomy is considered to be the treatment of choice. In Case 5 it was not done because the diagnosis of leiomyosarcoma was not made at the time of operation even though a curettage was performed. In Case 6 the cervix and surrounding tissues were intimately involved in the tumor, and the cervix was therefore left behind.

Two patients received x-ray therapy postoperatively. One (Case 4) was noted at operation to have metastatic involvement of the iliac and low aortic lymph nodes. During the first three weeks postoperatively these areas were treated with 2400 r of x-ray therapy given to each of two portals. The patient died in eight months without evidence of improvement due to radiation. In Case 6 tumor

In spite of reasonably prompt surgery after the onset of symptoms most of the patients had advanced disease when explored. One had polypoid masses filling the entire endometrial cavity, with extension to an ovary. Three others had large masses 10 cm or over in diameter, with extension outside the body of the uterus. The masses in the remaining 3 cases were 3, 4 and 5 cm in diame-

FIGURE 3 *Leiomyosarcoma in Case 7*

*This shows a relatively benign growth resembling a very cellular fibroid but lacking a capsule as it encroaches on the blood vessel above.*

FIGURE 4 *Leiomyosarcoma with Slight Variation in Cell Morphology (Case 3)*

ter. Of these patients 2 (Cases 5 and 7) are living and well after one and four years, and another (Case 2) died of other disease in five months. This indicates that early lesions have a rather favorable prognosis.

Evans,<sup>8</sup> in a painstaking study, was able to show that the prognosis of leiomyosarcoma bears a relation to the number of mitotic figures in a given lesion. He divided his 72 cases into three groups according to the number of mitoses and found excellent results in those with no or very few mitoses per cubic millimeter. In the series reported in this paper there were 3 such cases. One patient (Case 4) had a tumor that had too great local extension for complete removal when she was first seen. Two others (Cases 5 and 7), as mentioned above, had small tumors (Fig. 3) and are living after one and four years. Presumably, tumors with few mitoses grow slowly and are discovered in many cases when still of small size.

It was also found that some of the larger tumors presented a varied histology, certain areas being much more anaplastic and widely growing than others. This suggests that sometimes areas of low-grade malignancy give rise to more rapidly growing tumor tissue with numerous mitoses (Fig. 4 and 5).

left in the region of the cervix did not respond to 2150 r given within three weeks of operation. This patient also died of the disease in six months.

On the whole these patients were operated on soon after symptoms appeared. Four had had symptoms for less than three months, 1 for three and 1 for four months, and 1 for two years.

Bleeding, pain and abdominal mass were the most frequent complaints, the major symptoms being as follows: bleeding, 2 cases, mass, 2 cases, pain, 2 cases, and bleeding, pain and mass, 1 case.

None of these tumors seemed to arise from the cervix. Only one of them was found associated with fibroids. This supports the views of Evans<sup>8</sup> and others, as opposed to the still popular concept that leiomyosarcoma arises from pre-existing leiomyoma. That such an occurrence is possible is not doubted. Indeed, Novak and Anderson<sup>3</sup> presented a photomicrograph of a leiomyosarcoma within a leiomyoma. It seems likely, how-

was performed, and a large specimen of leiomyosarcoma obtained. In the absence of other demonstrable metastasis a shoulder-girdle amputation was advised. This operation is understood to have been performed elsewhere. The patient is still living at the present writing.

This case presents several interesting aspects. The tumor did not recur clinically for four and a half years. Metastasis to bone is very rare in these tumors. Histologically, the original tumor presented many striking characteristics. Most of it was of a low grade of malignancy without mitoses (Fig. 4). Other regions presented a chaotic appearance, with numerous giant cells and vacuolated cytoplasm. This finding alone is of little note, but the presence in certain areas of numerous bizarre mitoses in association with giant cells (Fig. 5) fore-

FIGURE 5 *Highly Malignant Area, with Bizarre Mitoses from the Tumor Shown in Figure 4*

ever, that most of the tumors are malignant from their inception.

The following case is presented in detail because of interesting points in the histology of the tumor, and the course of the disease.

**CASE 3** E. R., a 48-year-old woman, was admitted to the hospital on October 16, 1941, with a complaint of a low abdominal tumor of 4 months' duration.

Physical examination was not remarkable except for a mass rising out of the pelvis to the umbilicus. A preoperative diagnosis of leiomyoma of the uterus was made, and a supravaginal hysterectomy and bilateral salpingo-oophorectomy were done on October 20. The immediate postoperative course was not remarkable. A pathological diagnosis of leiomyosarcoma of the uterus extending into the left parametrium was made.

In May, 1942, the patient noted a lump in the neck, and a substernal thyroid gland containing multiple adenomas was removed.

When seen on March 11, 1946, the patient had no complaints. On her next visit, 1 year later, she stated that she had been having increasing pain in the left shoulder since the last check-up. There was a tender swelling in the region of the head of the humerus, and x-ray examination showed a cystic mass, with a pathologic fracture, expanding the upper end of the humerus (Fig. 6). The roentgenogram was consistent with a benign giant-cell tumor of bone except that the cortex was broken in places. Metastasis from cancer in the thyroid gland was suspected inasmuch as it is well known that a malignant lesion may be missed in the pathological study of apparently benign adenomas of the thyroid gland. On March 24, 1947, an aspiration biopsy of the bone tumor

FIGURE 6 *Metastatic Leiomyosarcoma of the Humerus Simulating Benign Giant-Cell Tumor of Bone (Case 3)*  
*This tumor appeared four and a half years after removal of the primary growth*

casts a poor prognosis according to Evans<sup>8</sup>. This was subsequently borne out.

Table 2 presents the pertinent data in 11 cases of stromal-cell tumors or mixed tumors of various types. Of these cases the last (Case 18) is considered separately. Of the other 10, the tumor was inoperable in 1 because of widespread disease. Four more could be treated only by exploration or partial removal of the tumor, and 1 had an inadequate follow-up study. Of the remaining 4 patients, who

were regarded as possibly cured at the time of operation, 2 had recurrence in eleven and eighteen months, and 2 are living without positive evidence of recurrence after five and thirteen years. One of these

eradicated by radiation. The patient is alive and well five years postoperatively.

Another patient (Case 14) had a much more extensive carcinosarcoma for which she received pre-

TABLE 2. *Pertinent Data in Patients with Sarcoma of Various Types*

CASE NO.	AGE	PATHOLOGICAL CLASSIFICATION OF TUMOR	TREATMENT	PERIOD OF SURVIVAL	REMARKS
8	63	Mixed mesodermal sarcoma with striated muscle	Panhysterectomy and bilateral salpingo-oophorectomy	—	Patient followed for only 2 months
9	56	Mixed mesodermal sarcoma with cartilage	Supravaginal hysterectomy	13 yr	No recurrence; patient still living.
10	68	Mixed mesodermal sarcoma with cartilage	Corectomy and radium	11 mo.	Tumor inoperable; gross tumor not completely removed; patient stated to have died of carcinoma of stomach.*
11	60	Mixed mesodermal sarcoma with myxomatous tissue	Exploratory laparotomy and biopsy	3 days	Gross tumor not completely removed; patient died of sarcoma and bronchopneumonia.
12	70	Carcinosarcoma	Radium preoperatively; par hysterectomy and bilateral salpingo-oophorectomy	5 yr	No recurrence; enlarged liver observed 1 yr after operation (possible metastases); patient living.
13	56	Carcinosarcoma	Wertheim hysterectomy and x-ray therapy for recurrence	38 mo.	Recurrence after 18 mo.; patient died of sarcoma.
14	72	Carcinosarcoma with striated muscle	X-ray therapy preoperatively; panhysterectomy and bilateral salpingo-oophorectomy	5 mo	No recurrence; patient living.
15	66	Stromal-cell sarcoma	Panhysterectomy and unilateral salpingo-oophorectomy; x-ray therapy (2412 r) postoperatively	3 mo	Gross tumor not completely removed; patient died of sarcoma.
16	51	Giant-cell sarcoma†	Radium preoperatively; exploratory laparotomy and biopsy	5 mo	Gross tumor not completely removed; patient died of sarcoma.
17	58	Giant-cell sarcoma†	Panhysterectomy and bilateral salpingo-oophorectomy	23 mo.	Recurrence after 11 mo.; patient died of sarcoma.
18	34	Sarcoma botryoides	Hysterectomy	4 mo.	No recurrence; patient living.

\*Cause of death given in city report; death may have been due to sarcoma.

†Tumor probably of stromal-cell origin.

(Case 9) had a mixed mesodermal tumor containing cartilage and lining the endometrial cavity to a depth of 2 cm. The other (Case 12) had a carcinosarcoma with a very small base in one horn of the uterus.

All these tumors lined or projected into the endometrial cavity. Some of the smaller ones assumed polypoid characteristics. Unfortunately the series is too small for any conclusions to be drawn regarding the relation of gross or microscopical findings to prognosis. It can be determined, however, that the chief cause of the low survival rate is the silent nature of many of the tumors. One of the largest, reaching to the umbilicus, caused only a distended abdomen for three days prior to hospital entry, and several other patients had equally large tumors after less than two months of symptoms.

Two patients who received preoperative radiation furnish concrete evidence of the effects of this form of therapy on the tumors. The first (Case 12), a seventy-year-old woman, was curetted, and 2450 mg. hours of radium was applied within the uterus three weeks prior to hysterectomy. The operative specimen contained three free portions of necrotic tissue, which had apparently been attached to a ragged area in one horn of the uterus. This region also presented much necrotic material. No viable tumor cells were visible in any of the routine sections. It seems fairly obvious that this was a pedunculated sarcoma and that it had been completely

operatively a total of 2190 r through each of three portals. This was given in two courses during the seven weeks before operation. In the specimen the

FIGURE 7. Carcinosarcoma (Case 13) Showing a Small Area of Carcinoma Occurring in a Predominantly Sarcomatous Tumor.

centers of the larger tumor masses were necrotic, but peripherally the tumor was widely infiltrating the myometrium.

In still another case (Case 16), 1600 mg hours of radium was applied within the uterus preoperatively. Twenty days later at laparotomy the tumor was too widespread (Fig 1 and 2) for removal to be attempted, and material was not taken for histologic study at that time. The patient in Case 10 had an inoperable pelvic mass, and the only therapy was diagnostic curettage and radium. Unfortunately the exact dosage is not given, and the effect

presented in some detail because of the previous radium and because the courses are typical of those seen in patients with similar lesions.

**CASE 9** G B, a 48-year-old woman, in September, 1924, received 1000 mg hours of radium for menopausal bleeding. Two 50-mg capsules of radium in tandem were left in the body of the uterus for 10 hours. A curettage produced insufficient material for biopsy. The patient was well until 9 years thereafter, when she began to have episodes of right-lower-quadrant pain. She reported for treatment 7 months after the onset of symptoms, when the uterus extended two fingerbreadths above the symphysis pubis. A complete hysterectomy was done on December 31, 1934, and a mixed mesodermal tumor removed with the uterus. The uterus was lined by a ragged, necrotic, friable tumor measuring up to 2 cm thick. Microscopically it was composed of undifferentiated, round cells with numerous areas of fairly well formed cartilage.

The patient was alive and well thirteen years postoperatively.

**CASE 13** A G, a 50-year-old woman, was given 1400 mg hours of radium for menopausal bleeding in January, 1937. Curettage produced endometrium diagnosed as hyperplastic. She was well from that time until May, 1943, when she was admitted to the hospital after 2½ weeks of vaginal bleeding

FIGURE 8 *Carcinosarcoma (Case 13), Demonstrating Another Area from the Tumor Shown in Figure 7*

of the radium on the size of the growth is not recorded. The patient survived eleven months.

In Case 15 x-ray therapy (2412 r) was given through each of two portals postoperatively because at operation small seedings of tumor were noted on the small bowel and in the liver. The patient died in three and a half months without showing improvement at any time. The patient in Case 13, described in greater detail below, received little or no benefit from x-ray therapy for recurrent tumor.

From the above cases, and the 2 patients with leiomyosarcomas previously mentioned as having received radiation therapy, one concludes that palliative roentgenotherapy is of little if any value unless it is to give the patient hope. The findings in Case 14 suggest that, as in carcinoma of the endometrium, preoperative radium destroys tumor projecting into the uterine cavity and thus prevents its dissemination in the operative field when the uterus is removed.

The following cases are of great interest in that the patients were treated with radium six and nine years prior to discovery of the sarcomas. Although the possibility seems remote, an etiologic role of the radium must be considered. These cases are

FIGURE 9 *Sarcoma Botroides (Case 18), Showing the Peripheral Grape-Like Projection*

On May 21 a morcellation of what appeared to be a submucous fibroid presenting at the cervical os was done. Microscopically this turned out to be a sarcoma, which was called stromal cell. On June 4 a Wertheim hysterectomy was performed, and histologic examination revealed a few areas of epithelium (Fig 7 and 8), the diagnosis was carcinosarcoma.

The patient had a local recurrence of tumor in 18 months and died of the carcinosarcoma 38 months after hysterectomy. X-ray therapy given on two occasions did not seem to influence the slow progression of the recurrent tumor.

The following case is also presented in some detail. Unfortunately, only four months have elapsed since operation and the ultimate outcome is uncertain, but the tumor is interesting enough histologically to warrant some discussion.

CASE 18. J S, a 514-month-old infant, entered the hospital on January 15, 1947. She had been healthy from birth until 5 hours before admission, when she had a sudden onset of profuse vaginal bleeding. She appeared normal except for a firm globular mass rising out of the pelvis to the umbilicus. Bleeding continued, and on the 2nd day a laparotomy was performed as a life-saving measure. The uterus was found enlarged and was opened in the midline, exposing a soft, grape-like mass of tissue measuring 5 by 5 by 0.8 cm. This was evacuated, leaving a smooth-lined endometrial cavity. A pathological diagnosis of sarcoma botroides was made and further surgery was advised but refused by the parents in view of the poor prognosis regardless of treatment. The child was alive without evidence of recurrence 4 months post-operatively.\*

Sarcoma botroides usually arises in the portio of the cervix and extends down into the vagina. In Case 18 the tumor filled the corpus uteri. Inasmuch as the exact origin of the tumor was not visualized at operation, but the entire endometrial cavity was smooth, it is assumed that the tumor arose from the cervix and for some reason protruded up instead of down.

Striated muscle fibers in a tumor of this type are considered pathognomonic of sarcoma botroides. They cannot be shown in this case but other characteristics are quite in accord with this diagnosis. Several areas within the tumor are of great interest histologically, since they help clarify the histogenesis of this tumor and possibly of others. There are large areas of a loose myxomatous tissue. The grape-like projections consist of closely packed cells with uniform, round, ovoid nuclei and little cytoplasm surrounded by cuboidal epithelium (Fig 9). Most noteworthy are areas of tubules lined by columnar or pseudostratified epithelium (Fig 10). These tubules closely resemble those of a fetal nephros, and structures simulating glomeruli can be picked out.

Wilms,\* in 1899, advanced the theory that mixed sarcomas of the uterus originate in displaced myotome and sclerotome elements carried down by the wolffian ducts. Glass and Goldsmith<sup>10</sup> concur in this opinion, and Case 18 seems to offer further support.

### SUMMARY

A brief account of the characteristics of various types of uterine sarcomas is given.

Eighteen cases treated at the Rhode Island Hospital since 1929 are recorded, and their classification is discussed.

A generally poor prognosis is recorded. The importance of few mitotic figures as evidence of a favorable outlook in leiomyosarcoma is supported.

There was a lack of evidence that leiomyosarcomas arise from pre-existing leiomyomas. In only 1 case were the two types of tumors found to coexist.

\*Information received after the preparation of this paper indicated that the patient developed a suprapubic mass ten months post-operatively and passed tumor tissue by vagina two months later.

Eight patients received radiation therapy of some sort. X-ray treatment seems to be of little palliative value. One case appeared to be favorably influenced by preoperative radium applied to the uterus, as evidenced by necrosis in the subsequent pathological specimen.

Four cases reported in detail comprised a leiomyosarcoma with late metastasis to the humerus, a

FIGURE 10. Sarcoma Botroides (Case 18) Showing an Area Resembling Wilms' Tumor of the Kidney

mixed mesodermal sarcoma and a carcinosarcoma occurring after radium treatment of menopausal bleeding, and a sarcoma botroides in an infant.

I am indebted to Dr. George W. Waterman for his advice in the preparation of this paper and to Dr. B. Earl Clarke for guidance in the study of the pathological material.

## THE PONDVILLE STATE CANCER HOSPITAL, 1927-1947

GEORGE L. PARKER, M.D.\*

NORFOLK, MASSACHUSETTS

SHORTLY after World War I, a movement was instigated in Massachusetts to provide care and treatment for patients with cancer. For many years various persons prominent in both public and private life became interested in the problem. The health officials believed that this was outside the realm of Public Health, but the public demands for some kind of a state-wide cancer-control program were so great that the Legislature in 1926 passed an act "to promote the prevention and cure of cancer and the extension of resources for its care and treatment." The bill originally called for the expenditure of \$1,500,000 for the construction of a modern hospital to be located in or around Boston, but for some reason, no money was appropriated when the bill was passed. At that time there existed in the town of Norfolk, twenty-two miles south of Boston, on Route 1-A, a group of vacant buildings known as the Norfolk State Hospital, — formerly used by the Massachusetts Department of Mental Health for the rehabilitation of narcotic and alcoholic habitués, — which could be renovated and utilized for the proposed state cancer hospital. Therefore, the Legislature amended the original bill and appropriated \$100,000 to renovate this group of buildings. Thus, Massachusetts became the first state in the country to appropriate funds for the construction and maintenance of a hospital to be used solely for the diagnosis and treatment of cancer.

The Massachusetts Department of Public Health, under mandate of the Legislature, opened the Pondville State Cancer Hospital on June 21, 1927. At first there was some question whether its 90 beds could be filled, but within a year the hospital was filled to capacity and had a large waiting list. Because of the demands, an addition for 25 beds was constructed, which only made a dent in the waiting list. The medical staff consisted of a medical superintendent and 4 residents, all graduates of surgical or rotating services of general hospitals. The nursing, in charge of a superintendent of nurses, was carried on by 19 graduate and 31 attendant nurses. A training school for attendant nurses was conducted with a course of one year. The visiting staff was made up of 17 men, all working on the cancer problem in other institutions in Boston or elsewhere, but none of them limiting their work to cancer.

The Pondville Hospital today has a capacity of 139 beds. These beds are in pavilions, each hav-

ing numerous single rooms and several 2-bed and 4-bed wards. These pavilions have large airy porches, comfortable rooms and the necessary diet kitchens — in fact, all that helps to make a person who is ill and away from home and friends more comfortable. There are four operating rooms with equipment of the most modern type, two deep-x-ray-therapy machines, which are now considered essential in the treatment of cancer, a gram of that very expensive but very necessary element, radium, numerous radium needles encased in platinum and an electrosurgical unit. There are also chemical, bacteriologic and pathological laboratories, all essential to a modern hospital, and a medical library to keep the members of the staff informed of world trends in the progress toward the solution of cancer. Practically from its opening, this hospital has been approved by the American Medical Association and the American College of Surgeons, an indication that it meets in all particulars the exacting requirements of an up-to-date hospital.

The visiting staff, composed of 27 men representing all the medical and surgical specialties, receive salaries from the Commonwealth. Many of these men devote two and a half days a week to the work of the hospital, and others half a day, still others are called as the occasion arises. These men are all working on cancer in other institutions and are deeply interested in its problems. The resident staff consists of the medical superintendent, who lives on the grounds, and 10 resident physicians, all men who have graduated from surgical and rotating services of general hospitals.

One of the important services of this hospital is the general clinic for new and ambulatory patients and for follow-up work. Here consultations are held by groups of visiting surgeons, with a radiologist, an internist, a dentist and a laboratory technician present to make the necessary examinations. No matter how advanced the case or how obvious the condition, thorough examinations by x-ray study and other special procedures are made. Special clinics are held on other days by appointment for follow-up work. As in any good state cancer-control program, it is necessary to have a central focus of activity, so does the Pondville Hospital act as a nucleus for seventeen state-aided cancer clinics situated in seventeen cities and towns. Cases difficult to diagnose are referred from the clinics to Pondville.

The Social Service Department at Pondville is also an important factor in its work because in cancer, as in every disease, the early diagnosis and

\*Superintendent, Pondville State Cancer Hospital

treatment depend not only upon the doctor's examinations and recommendations for treatment but also upon the patient's carrying out this advice. This, in turn, is dependent upon the patient's environmental conditions and economic resources, and it is here that the medical Social Service Department is of great value. The Social Service Department at the Pondville Hospital serves both the outpatients and the house patients. Thus, the Social Service Department, whenever possible, interviews the patient before he enters the hospital, assists him whenever and however possible while he is in the hospital and performs a valuable service in the follow-up work after he has been discharged. Uniform records are kept, and statistical studies are frequently made.

A volunteer social-service committee, comprising a group of women from neighboring towns, a local minister and a parish priest, provides many little luxuries for the comfort of both patients and employees. Recently, funds have been given to this committee by the Massachusetts Division, Incorporated, of the American Cancer Society to assist in the care and treatment of patients after they are discharged.

In 1928 the Legislature enacted a law regarding admissions and charges at Pondville. This act limits admission to residents of Massachusetts who have lived in the Commonwealth for at least twenty-four out of the last thirty-six months prior to the date of application and requires the written application of a registered physician or dentist. Persons who are able to pay their own bills pay \$10.50 a week. If a person is unable to pay, the city or town in which he has a legal residence is assessed at the rate of \$17.50 a week. Every patient, whenever possible, regardless of his financial status, is given a single room and as much individual attention as his condition requires. There is no classification of a ward or a private patient. The few wards of two and four beds are for patients able to be up and about. The Pondville personnel, from the lowest to the highest position, co-operate in giving the patient every service and in making him comfortable mentally and physically.

Daily visits are made by the priests and ministers from neighboring parishes, and current literature is distributed twice weekly for those requiring reading material. For those who enjoy the radio, bedside earphone attachments are available.

When a patient is discharged from the hospital, he is referred back to his family doctor or the clinic doctor who referred him to the institution. A letter is sent to this person giving the diagnosis, treatment and prognosis, with the advice that there be a continuous follow-up, both under his supervision and in the outpatient clinic of the Pondville Hospital. In this way harmony and co-operation are maintained between the hospital and the private physician.

TABLE 1 Total Cases of Cancer from 1927 through 1946

DIAGNOSIS	MALE PATIENTS	FEMALE PATIENTS

The purpose of the Pondville State Cancer Hospital is threefold to provide adequate care for patients unable to be accommodated elsewhere, to stimulate more adequate diagnostic and therapeutic service for cancer in clinics, and to train physicians, surgeons and nurses in the diagnosis, treatment and general care of patients with malignant lesions. During the past twenty years, under the supervision of four successive commissioners of public health and three superintendents, the Pondville Hospital has hospitalized 21,277 patients, of whom 14,015 were new cases and 7,262 were readmissions. During the early days, upon admission the majority of patients were in the advanced stages of the disease, whereas in the last decade most of the patients were early cases and represented a fair cross-section of cancer as it has occurred in Massachusetts. Major operations were performed in 18,325 cases. The total deaths num-

bered 3,453, and in 57 per cent of the cases permission for autopsy was granted. In the outpatient clinics 101,943 patients were examined, of whom 19,153 were new cases and 82,790 patients were follow-up cases.

have settled in Massachusetts, and the others have settled in twenty-two states and three different countries. Many of these men have returned to their native states to practice and, so far as can be learned, are doing their share of the cancer work in their respective localities. This is particularly true of the 56 physicians who have settled in Massachusetts. Four surgeons have died, and the status of 11 other men is unknown.

Table 2 shows the location by country and state. Fifteen years ago, the late Dr. George H. Bigelow, then commissioner of public health, and Dr. Her-

bered 3,453, and in 57 per cent of the cases permission for autopsy was granted. In the outpatient clinics 101,943 patients were examined, of whom 19,153 were new cases and 82,790 patients were follow-up cases.

Table I includes all cases that were diagnosed as malignant, and since the members of the visiting and resident staffs have reported the results of the treatment given these patients in the current medical and surgical journals during this twenty-year period, no attempt is made to analyze these figures.

The Pondville Hospital, to date, has not only completed the first two of the original purposes for which it was established but also trained 124 physicians and surgeons in the specialized treatment of malignant tumors. Of these, 21 men received special training in pathology. Many of the men

FIGURE 1 Expenditures vs Income Over Twenty-Year Period

bert L. Lombard, director of the Division of Cancer and Other Chronic Diseases in their book entitled *Cancer and Other Chronic Diseases in Massachusetts* wrote "to give what would seem to be the most intelligent service in the field of recognition, cure, and alleviation, costs hundreds of thousands to millions of dollars." Truer words were never written, for the service rendered by Pondville during the last twenty years has cost the Commonwealth over \$5,500,000, and

this figure does not include the cost of additional building construction during this period. To be sure, more than \$1,250,000 was collected from patients and the public-welfare boards in the various cities and towns as prescribed by the legislative acts of 1927, but the collections never balanced the expenditures (Fig 1).

Figure 2 illustrates the fact that during the last six years the strictly indigent patient has been in the minority, for the greatest income has been collected from private sources—that is, from the

FIGURE 2. Patient Income vs Income from Cities and Towns over Twenty-Year Period.

patient. However, the charge to the private patient represents only a fraction of the cost of treatment, and the greater part of the patients admitted are in fact medically indigent.

The ravages of World War II not only produced an increase of hospital expenditures but also caused a great upheaval in our hospital personnel. Like many other institutions, Pondville has been forced to decrease its active bed capacity to 40 patients because of the lack of graduate and attendant nurses. In spite of these factors, the turnover of patients in the hospital and in the outpatient clinics reached approximately prewar figures (Fig 3). This was due to the careful selection and screening

through the general clinic of the cases admitted to the hospital.

Table 3 explains the preceding charts and demonstrates the hospital activities on a yearly basis,

FIGURE 3. Proportion of Active Beds vs Available Nurses and Decrease in Average Period of Hospitalization over Twenty Year Period.

with special reference to the average number of house patients, the average period of hospitaliza-

tion, the average number of available employees and the outpatient clinic visits

The peak of the patient and employee load was reached in 1938, and although the patient load fluctuated because of the type of cases admitted, the employee load remained constant until the year 1942. At this point the effects of World War II began to be felt, especially the lack of nursing personnel, and, consequently, only such patients were admitted as could be efficiently and adequately handled. It will be noticed that the average period of hospitalization reached a peak in 1930 and dropped annually to the low level of nineteen days, whereas the total outpatient visits steadily increased annually up to 8085. In passing, it is of interest that the daily cost to the Commonwealth for these services in the early days was five dollars per patient day. Twenty years later, and particularly during the post-war period, this figure has been multiplied many times.

The people of the nation, particularly the citizens of Massachusetts, laymen as well as physicians, have become more conscious of cancer during the

last five years, and public opinion, having been aroused, has resulted in not only a greater need for beds for the cancer patient but also a demand for more intensive cancer investigation. In 1947 the Legislature, to meet the local needs, approved the expenditure of \$600,000 for the construction of a power plant and a 100-bed nurses' home and recreation building. The Massachusetts Department of Public Health has recommended to the Legislature the expenditure of over \$2,000,000 for additional buildings during the next five years to keep Pondville abreast of recent developments in the prevention and treatment of cancer.

Massachusetts citizens should be proud of the progress that the Pondville State Cancer Hospital has made in the battle to eliminate one of the greatest killers. For twenty years it has been the leader in this fight, and today stands as a tribute to those who worked so earnestly to make possible modern hospitalization for all its citizens who are in need of its services.

## UNUSUAL REACTION TO PENICILLIN IN OIL AND WAX

CLARENCE E. BURT, M.D.,\* AND SHELDON M. CAPLAN, M.D.†

NEW BEDFORD, MASSACHUSETTS

AS new forms and combinations of penicillin have been developed, the reported incidence of hypersensitivity has also increased. Keefer<sup>1</sup> states that the incidence of hypersensitivity following the use of amorphous penicillin in aqueous solution has varied between 2 and 5 per cent. Although there is a belief that hypersensitive reactions are somewhat greater when penicillin in peanut oil and beeswax is used, conclusive evidence is not yet available.<sup>2</sup> Beeswax itself has been regarded as nonantigenic,<sup>3</sup> but some authorities think that certain persons may become sensitized to it.<sup>1</sup> Extensive studies have failed to show that pollen extracts are carried over in beeswax.<sup>2</sup> Some evidence has accumulated that the sensitization is to the penicillin itself and not to the oil and wax, for patients who receive penicillin in aqueous solution, after being sensitized by use of penicillin in oil and wax, have typical allergic reactions.

Romansky,<sup>4</sup> in a series of approximately 4000 cases treated with penicillin in oil and beeswax, reported allergic reactions in about 5 per cent. The reactions varied from slight urticaria to edema of the angioneurotic type. These reactions reached a maximum within four days of appearance. If the injection was given subcutaneously a local reaction occurred more frequently. Heat to the area

aggravated the symptoms, whereas cold and the antihistaminic drugs gave relief. Thus, it appears that these reactions were truly allergic ones and not due to tissue injury. The Arthus phenomenon—local edema and necrosis following subcutaneous injection of the specific antigen—has not been reported.

Lederman<sup>5</sup> reported a case of severe local reaction after ten injections of penicillin in oil and beeswax, a total of 3,000,000 units having been given prior to the reaction. Another manufacturer's product did not give a reaction when the injections were resumed. Switzer<sup>6</sup> reported an acute local reaction one week after a single intramuscular injection of 300,000 units in a patient who had previously taken penicillin lozenges. In our practice 2 cases have exhibited urticaria and pruritus seven to nine days after a single injection of penicillin in oil and beeswax, no history of previous penicillin usage could be established. The third case is so unusual that it is reported in detail.

### CASE REPORT

A 29-year-old married man was first seen on November 18 complaining of a furuncle of the left nostril, which had first been noticed on the preceding morning and had rapidly increased in size by the late afternoon. The only treatment had been hot compresses.

The past history was essentially irrelevant except for hypersensitivity to ragweed, which was controlled by pre-seasonal and co-seasonal desensitization treatment as well as antihistaminic drugs.

\*Member, medical staff, St. Luke's Hospital, New Bedford and Acushnet Hospital, Acushnet, Massachusetts.

†Member, medical staff, Union Hospital, New Bedford, and Acushnet Hospital, Acushnet, Massachusetts.

Physical examination disclosed a furuncle the size of a small lima bean in the left nostril; the surrounding area was inflamed, firm and very tender. The nostril was almost completely occluded by the furuncle.

The temperature was 99.2 F.

At 9 a.m. the patient was given 300,000 units of penicillin in oil and beeswax (Romansky) intramuscularly in the anterior aspect of the midportion of the left thigh. Soon afterward some pain was present at the injection site. At 3 p.m. the area from there down to the left knee was tender in the touch and active motion was painful. Three hours later the area was so sensitive that the weight of a blanket caused pain and motion was not possible. The temperature was 99.6°F., and headache and malaise were present. No signs of injury or tissue damage were visible, nor was there any change in the size or contour of the involved area. Treatment consisted of bed rest with ice packs and salicylates.

On November 19 the pain had diminished slightly and some active motion was possible. Serous exudate was present at the left knee joint; the entire area otherwise appeared normal. Weight bearing was painful. Since the furuncle was still inflamed and firm the patient was given 100,000 units of crystalline sodium penicillin G in aqueous solution into the right buttock. No immediate hypersensitive reaction followed. Another similar injection was given on the following day without reaction. In the next few days the symptoms gradually disappeared except that the left knee hurt on walking. The furuncle was healed on November 23. Treatment for the left knee-joint exudate was ice packs since heat aggravated the symptoms.

On the 9th day after the initial injection the entire area suddenly developed a pruritic urticaria, and the left knee joint exudate reappeared. Pyriminexamine in 50-mg doses controlled the pruritus. By November 28 the left thigh was 3 cm. larger than the right, and the skin on the anterior aspect had a thick, doughy texture. Very little pain was present, and normal activity was possible. On December 1 the left ankle was also swollen, being 2 cm. larger than the right. The left thigh was enlarged 2.5 cm. and the calf 1 cm. All edema was gone on December 5, and the only residuum was a noninflammatory, red area at the site of the injection on the right buttock.

### DISCUSSION

Since the patient denied having previously received penicillin in any form, he was questioned regarding his allergic history in an effort to establish an allergic basis for the early acute reaction. He stated that at least once each summer,

during the period of ragweed allergy, the left knee joint became edematous and remained so for several days. Thus, one etiologic source in this case may have been the presence of ragweed pollen in the beeswax, although such pollen has not been found in beeswax in previous studies.<sup>2</sup> A second possible cause may have been an early serum-sickness type of reaction to the penicillin. Kendig and Toone<sup>7</sup> reported 3 cases in which a serum type of reaction developed five to seven days after oral administration of penicillin had been discontinued. These were delayed reactions characterized by fever, sensitivity to touch and swelling of the wrist and ankle joints. There are no reports in the literature on reactions to penicillin as early as that in the case described above.

### SUMMARY

A case of both acute early and delayed reactions to penicillin in beeswax and peanut oil is presented. Two possible etiologies are suggested.

## MEDICAL PROGRESS

### PILONIDAL CYST AND SINUS

JOSEPH LIBURT, M D \*

HUNTINGTON, NEW YORK

THE ideal of all surgical treatment is to effect a cure, and in pilonidal cyst and sinus the basic aim is to prevent recurrence, lessen the period of disability and obtain a good mechanical result. The various methods presented in the literature by skillful surgeons attest to the fact that the search is not easy, although a number of men seem to have found the key to the problem.

This paper, therefore, presents a review of the literature, with a follow-up of constructive criticism, and the presentation of my technic, which is considered a rational approach to the problem and has resulted in 100 per cent cures.

Naturally, one would be less than human if he did not think his method superior, especially if excellent or relatively excellent results were usually obtained. One may disagree with the other man's procedure, or hold it in light regard. But it is best to remember that a certain method may work well in the hands of one surgeon and yet prove disastrous when another attempts it with seemingly the exact technic — the reward going to the former, who may have used certain imponderable niceties and nuances in the successful performance of his task.

Those who find a certain method newfangled or bizarre should keep in mind the following thought well expressed by Cutler and Zollinger<sup>1</sup>:

Every change in the practice of surgery has aroused violent opposition. There was a battle between Lister and his opponents — the introduction of the x-ray elicited bitter criticism on the part of the conservative practitioners of that day. More recently the introduction of the electric scalpel and of the many forms of electricity for cutting and for coagulation has brought bitter opposition and slow acceptance.

The term pilonidal cyst or sinus, from "pilus" (hair) and "nidus" (nest), comprises an abnormal opening in the midline skin superior to the anus in the gluteal cleft over the sacrococcygeal region. The defect is lined with epithelium, and may contain cellular debris, hair and sebaceous material. Sharpe<sup>2</sup> has written the following description:

The tract is lined by poorly developed epithelium, and before the stage of infection, there may be some excretion of the products of skin metabolism through the orifice. If the orifice becomes blocked by accumulated debris or following an injury, the retained secretion may form a cyst or more commonly become infected and form an abscess. If the abscess ruptures without benefit of the surgeon, as is often the case, a fistulous opening is formed,

if it closes, a secondary abscess may form later, and so the process may be repeated several times before the patient seeks surgical relief.

According to Granet and Ferguson,<sup>3</sup> the term "pilonidal" is not necessarily correct, since most cysts do not contain hair. The authors state that the hair is extraneous and has its origin in the hair follicles of the skin of the natal fold adjacent to the sinus or dimple. Through the trauma of friction between the skin surfaces, some protruding hairs are broken off and retained in the sinus, through years of accumulation and by constant moulding from external pressure, they eventually become compressed and kneaded into hair nests.

#### TYPE

Gage's<sup>4-6</sup> classification is simple and clear: sacrococcygeal dimple and sacrococcygeal dimple and sinus, true pilonidal sinus confined to the subcutaneous tissue, true pilonidal cyst extending to the sacral canal, and true pilonidal cyst continuous with the subarachnoid space and canal of the spinal cord.

#### ETIOLOGY

Several interesting theories regarding etiology may help to explain the pathology and act as a guide toward rational treatment of this condition. Mallory<sup>7</sup> declares that the causation embraces the principle of captured ectodermal cells in the subcutaneous tissues and soft parts, the condition is due to captured ectodermal cells occurring at any stage during the development of the medullary canal or to faulty obliteration of the canal itself, or to a combination of both factors.

Weeder's<sup>8</sup> conclusion is that the included ectodermal cells may be limited to the soft parts, extending to and caught in the dorsal arches of the vertebrae, or may be continuous with or captured in the medullary canal, or the latter may leave unobliterated remnants either with or without spinal bifida occulta anywhere below the second sacral segment. They may extend to the skin through a sinus or remain as a cyst. It is interesting that Rogers and Dwight,<sup>9</sup> in a series of 400 cases, have found none to have communication with the neural canal, attesting to the rarity of this complication.

Fox,<sup>10</sup> in a detailed study, concludes that the pilonidal cyst is a congenital lesion due to a process of normal ectodermal invagination in the embryo,

\*Chief proctologist, Huntington Hospital.

which usually disappears but in these cases has persisted in adult life. It commonly contains fine, silky hair and mucoid or gelatinous material, it is almost always infected, and its walls consist of several layers of epithelial cells with glands and hair follicles. Derived from the budding or growth centers in the basal layer of the ectoderm that gives rise to hair follicles and glands, it consists of cells that form only hair and glandular appendages. For this reason, according to Fox, one never sees teratoma, neurogenic growths or heterologous tumors in pilonidal sinus.

Gage<sup>4</sup> is the chief proponent of the neurogenic theory; he believes that the condition is due to persistence of the neurenteric or neural canal. Normally, in the caudal end of the embryo, the portion of the neural canal that is formed by union of the neural folds and lies between the skin and coccygeal vertebrae is obliterated by cohesion of its walls, failure to do so forms a cavity, which may be connected with the skin by one or more sinuses. The lining of the cystic cavity retains the faculty of producing the primitive skin appendages: the hair follicle or shaft, and a rudimentary type of nervous tissue if a connection with the spinal canal remains. Gage regards this as the true origin of pilonidal sinus and believes that the sacral dimple is the result of an anterior pull on the overlying skin by the caudal ligament as the coccyx grows downward and curves anteriorly.

#### INCIDENCE AND DISTRIBUTION

Sharpe<sup>5</sup> states that 20 to 25 per cent of all infants examined at birth and about 4 per cent of a larger group of adults present either a distinct dimple or depression of the skin at the sacrococcygeal region. These always remain symptomless. Actual sinus orifices are seen less frequently, the exact incidence being unknown. The average age at which annoyance first occurs is nineteen years, with the incidence two or three times as great in males. McKirdie<sup>6</sup> states the incidence among Negroes as compared to that among whites to be 1.2150, or negligible, with no reports in the yellow, brown or red races.

#### DIAGNOSIS

The sinus consists of small midline openings over the sacrococcygeal region, with an occasional tuft of hair protruding from the opening. When the sinus is infected, pus may exude from the openings. The area may be red, swollen and indurated, showing signs of a superimposed abscess.

#### TREATMENT

##### Röntgen-ray Therapy

Smith<sup>12</sup> uses roentgen-ray irradiation to inhibit hair growth from interfering with healing.

control infection. He presented 6 cases in which the final results were inconclusive.

Turell<sup>13</sup> reported a case in which 675 r was applied to the perineum and sacrococcygeal area over a period of two months, the sinus closed shortly before cessation of the treatment, and remained closed for five months, thereafter the patient disappeared, making it impossible to observe him further for ultimate results. In another case, 650 r was used over a six-week period, and the sinus has remained closed to date (two years).

Sher<sup>14</sup> obtained gratifying results in cases with a small sinus and small discharge and in cases with a short clinical history.

##### Sclerosing Solutions

Cutler and Zollinger,<sup>1</sup> observing the successful use of fixatives by the neurologists for gliomatous cysts, became interested in such a method for pilonidal cysts and sinuses. In the 3 cases presented, the roof of the sinus was incised, the edges being protected with zinc oxide, and the cavity filled with 1 to 5 cc of modified Carnoy's solution (3 cc of absolute alcohol, 3 cc of chloroform, 1 cc of glacial acetic acid and 1 gm of ferri chloride). This was allowed to remain for five to ten minutes and then sponged out, and the destroyed tissue curetted away. This procedure was repeated every two weeks, at times daily, gauze was inserted after exposure to the solution.

Biegeleisen<sup>15</sup> presents 3 cases with a one-year cure. The sinuses are probed, and a modified Carnoy's solution is injected, a dull-tipped needle being used. Two weeks later the sinuses are curetted (2 per cent nupercaine being employed) with a fine curette or a needle having a long bevel, bent to form a slight hook, then fuming nitric acid is applied on an ordinary metal applicator deeply within the sinuses. Two weeks later this procedure is repeated. One month later it is difficult to enter the tracts, and still a month later the tracts are completely closed.

Mathesheimer<sup>16</sup> uses ethyl laminobenzoate (twenty-five parts) and phenmethylol (seventy-five parts). The abscess or sinus is opened under skin infiltration. The tract is opened on a probe or grooved director at different stages, so as not to cause too large a wound. The wound is swabbed out, and plain gauze, saturated with the solution, is inserted, this procedure is repeated until healing has reached the surface.

Knowlton<sup>17</sup> uses 10 per cent sodium morrhuate, injecting 2 cc, and repeats the procedure in three or four days. Of 4 cases presented, 4 were completely cured.

Heyd<sup>18</sup> excises an ellipsis of skin carrying all the "dimples" and packing the cavity with modified Carnoy's solution. The gauze is left in for forty-eight hours, and the patient is treated in a similar manner every 5 days, with plain gauze in the interim.

five cases were presented, all successful Heyd claims that this method makes the walls of the wound rigid and firm, and that the cavity heals readily and rapidly

Shafiroff and Doubilet<sup>19</sup> used a mixture of penicillin and sodium morrhuate (5 cc of 5 per cent sodium morrhuate to 100,000 units of dry penicillin), 1 cc was injected directly into the cyst or sinus tract the first time, and as sclerosing progressed, small amounts were injected daily and then every other day Twenty-seven cases were presented, with a minimum of four to a maximum of forty-six injections After two or three injections the drainage from the orifices subsided rapidly A follow-up study over a three-month period showed recurrences in 3 cases

### Cautery Excision

Rogers is a leading exponent of the use of the cautery knife In a series of 181 ambulatory cases this technic was employed by Rogers and Hall<sup>20</sup> The method, in brief, consisted in repeated excision with cautery of the diseased tissue The sinus was first divided longitudinally down to the sacrococcygeal fascia, and then removed in halves by slight undercutting of the skin edges Postoperatively, further fractional removals were effected for portions overlooked originally The loss of time from work was less than two weeks At the time of publication, Rogers and Hall believed that there was room for improvement In an article written in 1938 Rogers and Dwight,<sup>9</sup> concluded that it was not necessary to remove or expose the sacral fascia At that time, in a large series of cases of undisclosed number, 90 per cent were cured in less than fourteen weeks, 80 per cent in less than twelve weeks, and 64 per cent in less than ten weeks, with a minimum of five weeks In a 1940 publication, Rogers<sup>21</sup> recommended conservative cautery excision under a local anesthetic in the outpatient department. The sinus tract and hair nest were dissected out through the midline skin incision with the small cautery blade, the resultant narrow wound was packed with gauze The shortest healing time was four weeks, with an average of nine weeks One hundred and fifty operations were done between 1935 and 1937, 14 in the hospital and 136 in the outpatient department, and 97 per cent were cured by conservative excision, remaining cured for one to four years On this basis, Rogers is against large block excision

Hipsley<sup>22</sup> excises the sinus by cautery and then makes an incision 7.6 cm lateral to the wound above the ischial tuberosity in the line of the fibers of the gluteus maximus muscle, a flap of muscle sufficiently thick to fill the cavity and to reach the opposite wall through the tunnel without tension is freed, the wound being closed loosely

### Marsupialization

Dorland<sup>23</sup> defines marsupialization as an operation for hydatid or other cyst in which the tumor is opened, its contents emptied, and its edges stretched to the edges of the external incision The interior of the sac so formed suppurates and closes by granulation Buie,<sup>24</sup> one of the chief exponents of this method, argues that the deeper half of the lining of the cyst cavity, since it was originally intended to form skin, can be used to advantage in the surgical management of the problem The operation makes use of the deep half of these membranes, whether part of the unaltered cyst cavity, abscess cavity or fistulous channel Buie further adds "If there has been no destruction by inflammation or erosive changes within the walls of the cyst or sinuses, this membrane will possess practically the same histologic structure as that of true skin and is therefore peculiarly fitted for the purposes of the operation" He leaves intact the inner wall of the cyst and its branching tracts, the skin edges are sutured to the margins of the remnant of membrane that originally enclosed the cyst, the cyst having been first unroofed and the redundant skin edges and outer half of the cyst wall having been trimmed away The floor of the cyst then becomes the external surface

Brockbank and Floyd<sup>25</sup> recommend radiant heat for fifteen minutes twice daily to keep the wound dry and to encourage epithelialization, having returned 90 per cent of 168 patients to military duty in twenty-one to twenty-eight days with complete healing

Peterson and Ames,<sup>26</sup> Van Dyke,<sup>27</sup> Henning<sup>28</sup> and Nesselrod<sup>29</sup> are all enthusiastic adherents of this method Nesselrod gives the following caution "The most annoying problem, and one which is a source of embarrassment both clinically and statistically, is the occasional failure of mid-line healing" For this, he recommends bed rest, ultraviolet-ray therapy and surgical revision of the skin edges

(To be concluded)

In the hospital the patient was observed to be very dyspneic and after several days began to develop sacral edema and moist rales at the left base. He was given digitalis, and an electrocardiogram taken several days after the digitalis was started showed sinus tachycardia, with evidence of digitalis effect on the ST segments and T waves, but no definite diagnosis of cardiac disease could be made. His appetite was very poor, and a Levine tube was introduced into the stomach to force feedings. All physicians who saw the patient believed that he was quite ill, and one observer noted, "He is sicker than he looks." All efforts at therapy were to no avail, the patient began to vomit blood, became more dyspneic, gradually became unresponsive and expired quietly on the twelfth hospital day. The temperature had remained at normal levels throughout the hospital course.

#### DIFFERENTIAL DIAGNOSIS

DR EARLE M. CHAPMAN In brief, the Pathology Department has invited me to make a diagnosis—I would even say that they have defied me to make a diagnosis. This was a sixty-seven-year-old man, who complained of being ill for six months, with weakness and anorexia and, I should say, asitria (a loathing of food) and vague abdominal distress. A careful investigation, including physical, roentgenologic and laboratory examinations, failed to provide an adequate diagnosis or even to give a clue. There is one small clue—a series of what I call dissociated signs of some impairment of liver function. Perhaps it would be well to discuss the one positive set of signs that we have—namely, the changes in liver function. In the first place, we find that the Graham test was reported elsewhere as being normal, and yet in this hospital a brom-sulfalein test showed 38 per cent retention of dye in the serum, which is abnormal. There was urobilinogen in the urine and some bizarre-shaped red cells and stippled cells, but there seems to be very little evidence of blood destruction. The van den Bergh test was negative, and the prothrombin time very slightly elevated, almost normal, there was a depletion of the carotenoids, and some depression of the serum protein. What do these signs indicate? I cannot accept the diagnosis of cirrhosis. But it seems that, from these tests, cirrhosis of the liver certainly had been entertained as a likely diagnosis. This was reasonable because the description of the final illness clinically reads like cholemia. It sounds like liver failure—what I believe Europeans used to call cholemia.

There are two or three red herrings that cross the trail. One is the coughing of blood, and the other, the positive guaiac reactions in three stools, indicating a lesion in the gastrointestinal tract. The x-ray films did not reveal such a lesion, and yet this would again fit with the clinical impression of cirrhosis. Esophageal varices that were leaking

were considered, and this could also account for the final episode of the vomiting of blood. An alternative explanation for the stools is that the patient was swallowing sputum from the right bronchus that contained blood, and this would better explain the intermittent positive guaiac reactions in the stools.

What are some of the things that we have to consider? Let us go back to the past history. A prostatectomy was performed twelve years before admission. Did the patient have a malignant tumor that had arisen in the prostate and involved the urinary tract? I do not see any evidence on which to base such a diagnosis and so I discard it. Was it a primary malignant lesion arising in the right main bronchus? We have the signs of fluid at the right base, dullness, diminished tactile fremitus, and diminished whispered voice—in other words, not only fluid but occlusion of the bronchus leading into the right lower lobe. Apparently no x-ray films of the chest are available.

DR STANLEY M. WYMAN No, just of the colon.

DR CHAPMAN Considering the definite cardiac changes, peripheral edema and dyspnea, did the patient have some form of underlying heart disease? We are told that the electrocardiogram was normal. No one seems to have made the diagnosis of heart disease, but I seriously entertain the possibility that this man at sixty-seven had calcific aortic valves. Calcific aortic stenosis is often overlooked in the older age group, and the signs are quite variable. He had a harsh systolic murmur and an elevated blood pressure, and finally died, with some of the symptoms of congestive failure. He did not respond to treatment. In trying to put the facts together, having entertained the other possibilities, we must consider some form of heart disease.

We must also consider carcinoma of the pancreas—in the body, of course, because the stools were colored, and there is no indication that a tumor mass was felt. But we must consider a small carcinoma of the pancreas with metastases to the liver and perhaps the lung on the right side. Carcinoma of the body of the pancreas is one of the most difficult diagnoses to make on clinical grounds, and in the case under discussion, there was no pain of pancreatic distribution or other signs to indicate such a lesion.

We must think of some rare disease involving a limited area of the liver, causing dissociated signs. The only disease that I can think of is primary tumor of the liver—a hepatoma. If the patient had a primary carcinoma of the liver, we must in all likelihood suspect an underlying minor degree of cirrhosis. I believe Dr. Mallory has taught us that in primary liver tumor there is always the co-existence of some degree of cirrhosis.

DR TRACY B. MALLORY There was in all but one case in the records of this hospital

DR CHAPMAN I think that Dr Mallory will have to tell us what was wrong. I cannot say anything except a malignant tumor involving the liver because of the clues that I have mentioned. If I have to make a diagnosis, I shall say hepatoma—whether it spread into the right chest and perhaps produced fluid or whether there was a metastasis in the region of the bronchus with erosion, it is impossible for me to say. The patient may have had an underlying calcific aortic stenosis.

DR. WYMAN The examination of the colon was unsatisfactory as the record notes because of the extremely large amount of fecal material. One can outline the lower border of the liver, but the upper margin is lost. One cannot say that the liver is grossly enlarged from these films. The spleen does not appear to deform the splenic flexure, it lies in normal position. The bones show no definite evidence of destruction that I can see. I see no definite abnormal soft-tissue masses. It is impossible to exclude a lesion of the colon, however.

DR. CHAPMAN Was a gastrointestinal series done by you, with study of the second portion of the duodenum, the possibility of pancreatic involvement with tumor and ulceration being borne in mind?

DR. WYMAN No, it was done elsewhere.

DR. BRIANT L. DECKER How about a myeloma with involvement of the liver? The serum protein was in the upper limits of normal, and the albumin-globulin ratio was 1.1.

DR. CHAPMAN I have myeloma written on the border of my copy of the abstract. I thought it unlikely and that the change of protein was consistent with liver disease, and so I excluded myeloma. One has to think of it with the reversal of the albumin-globulin ratio, but as I say I prefer to let the liver take care of that.

DR. ALFRED KRANES I cannot think of a case of myeloma without anemia. I may be wrong about that. Is that correct?

DR. MALLORY Yes.

DR. GEORGE A. McLEMORE, JR. Could the high urobilinogen have been caused by the gastrointestinal bleeding?

DR. CHAPMAN I do not know, but I doubt it. That is all I can say.

#### CLINICAL DIAGNOSES

Liver failure, probably from portal cirrhosis  
Arteriosclerotic and hypertensive heart disease,  
with congestive failure

#### DR. CHAPMAN'S DIAGNOSES

Malignant tumor of liver (hepatoma?)  
Metastases to lung  
Calcific aortic stenosis

#### ANATOMICAL DIAGNOSES

*Adenocarcinoma of pancreas, with metastases to liver, lungs, left adrenal gland and serous surfaces*

Pulmonary emphysema

Hypertrophy of heart, hypertensive type

Thrombosis of segment of inferior vena cava and both common iliac arteries

#### PATHOLOGICAL DISCUSSION

DR. MALLORY Post-mortem examination showed extensive neoplasia. The pleural and abdominal cavities were both studded with minute tumor nodules. The lungs showed extensive involvement of the pleura, extending a very short way into the parenchyma of the lung, but nothing that suggested a primary tumor. The liver was small, weighing only 1500 gm., but showed a large number of very small tumor nodules. In the body and tail of the pancreas was a large mass of tumor—the only large mass that we found. The histology was entirely compatible with a primary pancreatic tumor. I do not believe there is much question about that. I still think that we have a very inadequate explanation of the peculiar laboratory findings as related to liver failure. It takes a great deal of cancer of the liver to produce any liver failure. Usually, when metastasis to the liver is extensive enough to cause liver failure, we find the organ grossly enlarged, weighing 3000 or 4000 gm. This liver was on the small side of normal. On the other hand, the total amount of tumor in proportion to the size of the persisting liver tissue was high. I suppose we must assume that the liver metastases were responsible for the liver failure. There was nothing to suggest any primary abnormality of the organ. The cells were in good shape, and there was no bile stasis, no fatty vacuolization or anything else that one could consider primary liver disease.

We did not find any evidence of calcific aortic stenosis though the heart was generally hypertrophied as in hypertension. There was a saddle thrombus of the vena cava extending into both iliac veins, but no pulmonary emboli of significant size.

DR. KRANES The laboratory findings in themselves are inconsistent. I did not believe that it was possible to have a normal cholecystogram with a bromsulphalein retention of 30 per cent. One or the other is wrong.

DR. MALLORY I think that there was a fair time interval between the two examinations.

DR. CHAPMAN Yes, the Graham test was done before he came in and the other was just before he died.

DR. JOHN STANBURY How much pleural fluid was there?

DR. MALLORY A few hundred cubic centimeters.

DR CHAPMAN Was there no gross area of erosion in the gastrointestinal tract?

DR MALLORY No, there was one small bronchus invaded by tumor, which might have accounted for the hemoptysis, but not for extensive bleeding

## CASE 34232

### PRESENTATION OF CASE

A fifteen-year-old boy entered the hospital because of a mass in the left calf

Five years prior to admission without antecedent trauma he noted the gradual onset of pain on the medial side of the left calf. It occurred only during exercise, was not severe and did not limit his activities in any way. Approximately three years before admission he noted a lump in this area, which was tender to touch. No particular motion caused pain, and there were no paresthesias. He noted that the heel of the right shoe wore out more quickly than the left. There was no weight loss or constitutional symptoms.

Physical examination showed a well developed and well nourished boy, the positive findings being limited to the left leg. There was full range of motion in the hip, knee and ankle except for dorsiflexion of the left foot, which was limited, the foot being held in about 15° of equinus. With the knee flexed the foot could be dorsiflexed an additional 10°, but it could not be brought into the normal amount of dorsiflexion, motion in plantar flexion was normal. There was no muscle weakness or sensory change. The knee jerks and ankle jerks were active and equal. The circumference of the calf was 12 cm less on the left than on the right. On inspection there was slight prominence in the region of the belly of the medial head of the gastrocnemius, and on palpation a mass could be felt in this same region, approximately 2.5 cm long and 1.5 cm wide. The mass appeared to be within or immediately beneath the gastrocnemius muscle. It was of firm consistence, nontender and not adherent to subcutaneous tissues or skin. No bruit could be heard. No lymph nodes were felt in the popliteal or inguinal regions.

The urine was normal.

X-ray examination of the leg was essentially negative.

On the second hospital day an operation was performed.

### DIFFERENTIAL DIAGNOSIS

DR JOHN A. REIDY With the information at hand we can at least decide why this boy wore his right heel out more than the left in that the Achilles tendon on the left was necessarily contracted, giving the equinus position as described in the x-ray

report. This kept the left heel from striking the ground or at least from striking the ground as firmly as the right. I venture to say that he probably had more wear on the toe and sole of the left shoe than on the right, although that fact is not mentioned. We can assume that the equinus deformity was probably due to contracture of the Achilles tendon, particularly in view of the fact that there were no changes in the foot or ankle. Motion was fairly complete except for this lack of motion in dorsiflexion, and since x-ray films of the foot are not mentioned I take it that they were normal.

We can now direct our attention, I believe, to the firm, nontender mass that lay beneath the medial head of the gastrocnemius muscle. It probably would be well to review the x-ray films.

DR STANLEY M. WYMAN I am sorry, but we do not have the films.

DR REIDY It would be worth while to know if there was a soft-tissue shadow—it might help in better localization of the lesion. If it was down the shaft distally beneath the gastrocnemius, it would present a different picture than it would if located beneath the gastrocnemius in the proximal portion in relation to the popliteal space, where there are numerous cysts, ganglions and so forth that arise from the posterior aspect of the knee joint. If the shadow were in relation to the knee joint, it might help us somewhat. The x-ray films apparently do exclude evidence of bony disease or tumor. We can therefore confine our thoughts more or less to the soft tissues.

This lesion was a chronic one, which had been asymptomatic for five years and palpable for three years. The size is mentioned as apparently remaining the same, although it may have increased. If it did, it certainly did not increase very much—2.5 by 1.5 cm is not a large lesion and can easily be obscured. The chronicity, the lack of pain and the good general health of the patient, I believe, are helpful in ruling out the possibility of any malignant tumor. Certainly, fibrosarcoma, which is one of the more common tumors in this region, would have manifested itself much more clearly and more definitely than this tumor.

Rhabdomyoma, a skeletal-muscle tumor, which I have seen in the medial head of the gastrocnemius, is a rare lesion and I doubt that it was present in this case. Certainly, it would have been more evident.

There have been reports of synoviomias removed from the region of the knee several years after the original tumor was noted. These are slowly growing tumors and could account for the symptoms in this case.

A low-grade infectious process such as tuberculosis, I think, is a remote possibility, but there is nothing to substantiate that diagnosis.

An organized hematoma or subsiding myositis ossificans could possibly have caused this difficulty. It is unlikely, however, particularly in view of the lack of trauma or changes on the x-ray films.

An angioma or aneurysm can readily occur in this region in relation to the popliteal vessel, but here again I think the tumor would have been soft, at least softer than that described, and would perhaps have caused a bruit, which is said not to have been present. Lipoma, similarly, is a soft tumor and probably would not have resulted in the irritation and pressure that caused this contracture of the Achilles tendon.

Chondroma is a possibility in that it can occur in the region of the knee joint, extend down beneath the gastrocnemius, and not cause a shadow by x-ray study, although there may be evidence of some soft-tissue distortion. That is unlikely, however, because it is such a rare lesion, as is a fibroma occurring alone. The fibroma is more likely to arise in the hand or foot than in this region.

There are other possibilities — either a Baker's cyst or a neurofibroma. Baker's cyst is an extension of the bursa that lies in relation to the semitendinous muscle and beneath the medial head of the gastrocnemius muscle and can dissect down beneath the muscle for a considerable distance. With the knee in extension this forms a dense, frequently nontender, tumor and may cause minimal or no symptoms. It is a possibility. Yet I think that a solitary, slowly growing, nontender neurofibroma, which is one of the more common tumors that occur in this region, can produce this picture, and on the basis of frequency I shall make that diagnosis.

DR. JOSEPH S. BARR: The mass was in the most prominent portion of the medial head of the gastrocnemius muscle, about 15 cm. distal to the knee joint. We did not believe that it was a ganglion or that it was related to the knee joint. The sole x-ray film taken was for the purpose of determining whether or not there was a soft-tissue mass, but

we could not see any. The mass was definitely palpable in or beneath the gastrocnemius muscle. Some years ago I had a patient, a boy about the same age, who had a tumor in this location that proved to be a hemangioma. The tumor in the case under discussion had no bruit and was hard and firm. I was a little indefinite in my preoperative diagnosis, finally settling for a tumor of the gastrocnemius muscle.

#### CLINICAL DIAGNOSIS

Tumor of gastrocnemius muscle, ? hemangioma

#### DR. REIDY'S DIAGNOSIS

Neurofibroma

#### ANATOMICAL DIAGNOSIS

*Cavernous hemangioma of head of gastrocnemius muscle*

#### PATHOLOGICAL DISCUSSION

DR. BARR: The tumor, which infiltrated the whole medial head of the gastrocnemius, was spindle shaped and quite firm. The tumor infiltrated the muscle and had no capsule, it involved at least half the medial head of the muscle. The whole of the medial head of the gastrocnemius muscle was excised.

DR. REIDY: Did you make a diagnosis on the gross specimen?

DR. BARR: I could not have, although we called Dr. Castleman to see it and he called it a hemangioma grossly. I believe that was the final diagnosis. It was a solid tumor with large blood vessels infiltrating into it. It was so solid that I questioned the diagnosis.

DR. TRACY B. MALLORY: Microscopical sections showed a characteristic cavernous hemangioma. The tumor was surrounded by a considerable degree of inflammatory reaction. The hardness may have been due to inflammation rather than tumor.

## ACUTE LEUKEMIA PRESENT AND FUTURE

IN an article published elsewhere in this issue of the *Journal* it is pointed out that the parenteral administration of certain folic acid antagonists is not infrequently followed by clinical and hematologic remissions in children with acute leukemia. The authors very properly stress the fact that these remissions, though somewhat prolonged, must not be regarded as cures.

Many years ago the hope was implied that acute leukemia was a potentially curable disease.<sup>1</sup> This hope and this belief stemmed from the undoubted fact that a moribund patient with unquestionable, acute leukemia went into a prolonged and complete remission after the parenteral administration of what was assumed (probably erroneously) to be adenylic acid. The remission was, however, almost certainly spontaneous, and the original disease re-

appeared in an explosive manner some five months later. In a very short time the patient was dead.

Subsequently a series of cases with acute leukemia of one sort or another with dramatic remissions of considerable duration was reported in the *American Journal of Cancer*.<sup>2</sup> Individual reports of similar remissions have appeared in standard medical journals from time to time, and still other patients have been seen but not reported. In one case a remission lasted approximately thirteen months. Some of these remissions appear to be truly spontaneous, occasionally they follow the subsidence of an acute infection. Of the 5 cases reported by Farber et al. initial remissions of this type occurred in 2.

Therefore, the possibility of a spontaneous remission must be entertained whenever a patient with acute leukemia becomes apparently well from both a clinical and a hematologic point of view. Yet so far as is known practically all such patients have subsequently died in relapse. Of the extremely rare case in which the patient did not die it may be said that the original diagnosis was incorrect.

Precisely what the bone marrow showed in these cases during the remission is not known, but as all lymphadenopathy and splenomegaly disappeared and the peripheral blood picture became entirely normal in all respects it may be assumed that the bone marrow in like manner and to like degree became normal.

This, then, is the first point: it is well known that spontaneous remissions—complete and of considerable duration—may occur in acute leukemia. It is not argued that the remissions referred to in the article under consideration were, in fact, spontaneous. It is simply pointed out that such remissions have occurred.

The second point is this: when the parenteral administration of a substance, of whatever nature, is followed by remission in leukemia one should be extremely cautious before one even implies that a true cure might result. The physician experienced in the care of leukemic patients and versed in the pitfalls of experimental work will scarcely be led astray. The practicing physician who does not specialize may grasp at this straw and overplay his hand. Believing that the earlier a case is treated the greater is the chance of success, he may treat patients whose

blood picture is suggestive of but not diagnostic of acute leukemia. And the layman — he who reads the daily press, which is no proper medium for the announcement of therapeutic measures still in their experimental stage — will not only grasp at the straw but also perhaps twist and turn even the most cautious expressions to his own supposed advantage. He may fail to distinguish between 'arrest' and 'cure', and he may brush aside as improbable or inconsequential the third point with the introduction of new therapeutic measures, even those of proved value, the beneficial effects stand prominently in the foreground and the deleterious and occasionally fatal side effects are either unrecognized or minimized. Such is the story of aminopyrine, arsenic for the treatment of leukemia, and sulfonamides and latterly folic acid.

There is some evidence, as yet unpublished, that the administration of aminopterin may be followed by refractory pancytopenia, and a similar sequence of events might follow the use of newer compounds as yet unsynthesized. It may be argued that such side effects as may occur in the treatment of acute leukemia with folic acid antagonists may be regarded as unimportant in view of the practical certainty of death in that disease. Yet whether these side effects may in themselves be fatal or permanent is not yet known, and, more important, the positive diagnosis of acute leukemia is not always easy. Physicians of international fame have been known to be wrong in its diagnosis. This being the case, it is possible that those who read the *Journal* might similarly be in error.

Clinical investigation must not be limited, and the early publication of experimental work should not be delayed once competent and unbiased observers believe the work to be well founded. It is proper and necessary, however, to be cautious to a fault.

The experimental data briefly and guardedly presented in this issue shed new light on the problem of leukemia, and we may, now, with some justice hope that aminopterin or some substance related to it, as yet unsynthesized, will afford a substantial basis for real hope in this now hopeless disease.

## MENTAL HEALTH AND WORLD CITIZENSHIP

The International Congress for Mental Health, to be held this summer in London, will have the formation of a world federation for mental health as one of its most important objects. The subject for discussion at this world congress — Mental Health and World Citizenship — will be broken down into five main headings: problems of world citizenship and good group relations, the individual and society, family problems and psychologic disturbances, organization, training and propaganda in planning for mental health, and mental health in industry and industrial relations.

To obviate the possibility of each group discussing its topic and arriving at its conclusions quite independently of the others — as might be the case if 'specialists' only took part in the discussions — mixed committees have been set up for the consideration of each subject. These committees will be composed of a variety of elements — psychologists, psychiatrists, sociologists, educators and anthropologists. Co-operating in plans for the Congress have been Dr. Brock Chisholm, executive secretary of the interim commission of the World Health Organization, and Dr. Julian Huxley, director general of UNESCO — the United Nations Educational, Scientific and Cultural Organization.

Dr. Chisholm, in a short paper published in *Surrey Graphic* in October, 1947, outlined the world's need for a supreme effort in the direction of more universal mental health. Man, in a physical sense, is becoming the master of his environment. The material obstacles to survival he has been slowly conquering, one by one — the hazards of climate, of inadequacy in food supply, of disease. The really great obstacle that remains is man himself with his highly developed intellect that he cannot use effectively because of his neurotic fears, his prejudices, his fanaticisms, his unreasoning hates, and equally unreasoning devotions.

This, paradoxically, is today the great threat to man's survival in a world that he has otherwise tempered to his needs — the presence of other men of other races, of other creeds, of other ideologies in

that world, and their inability to live in harmony together

So great a control has man today over various environmental situations that a few men of ill will may obtain the power of affecting the destinies of millions. A single pyromaniac may destroy a forest that has been a century in growing, a small nation may have the means of plunging a great one into chaos.

And so there is present the impelling need, the need above all others of finding a scientific, factual approach to man's difficulties, of bringing him to mental health and a mature viewpoint where he will have the power and the desire

*To strive, to seek, to find, and not to yield*

## THE MASSACHUSETTS CANCER PROGRAM

THE paper by Dr. George L. Parker on the Pondville State Cancer Hospital, which appears elsewhere in this issue of the *Journal*, brings memories to those of us who can say, "All of it I saw, some of it I was."

In gazing at the panorama of twenty years of cancer-control activities, one cannot but feel the absence of those members of the Massachusetts Medical Society who are no longer with us, but whose efforts aided in building the Massachusetts cancer program. Among them may be mentioned Thomas Almy, George H. Bigelow, Orrin C. Blair, Walter P. Bowers, Martin M. Brown, J. Forrest Burnham, Farrar Cobb, Francis G. Curtis, Robert B. Greenough, Thomas P. Hennessey, William T. Hopkins, Ernest L. Hunt, George A. Leland, Edward D. Leonard, G. Forrest Martin, William J. Pelletier, Charles H. Richardson, Walter Sawyer, Halbert G. Stetson, James S. Stone, Frederick Thompson, William L. Tracy and Philemon E. Truesdale.

To these and to others, the Massachusetts Medical Society, the citizens and the Department of Public Health owe much. The farsightedness, enthusiasm and willingness of these pioneers to devote time and energy to cancer control resulted in a program that has received nation-wide recognition.

In reviewing the accomplishments of the Program one remembers the establishment of the diagnostic clinics, the opening of Pondville Hospital, the inauguration of cured cancer clinics, the survey on

cancer and other chronic diseases, followed by the publication of the results in book form, the organization of the co-operative cancer-control committees in every town and city in the Commonwealth, which began in 1935 and extended over a period of years, the teaching clinics for the medical profession, the opening of the cancer wing at Westfield State Sanatorium, the Cancer Manual for Practitioners, sent free to every physician in the Commonwealth, the utilization of the Massachusetts Program for training representatives from other states and countries in cancer control, *The Procedural Analysis of the Compilation of Cancer Data for Statistical Uses in the Massachusetts Department of Public Health Cancer Control Program*, published by the United States Public Health Service and distributed to health departments throughout the United States, the surveys to evaluate cancer education, and the experiment on cancer education in the schools of Lynn and Malden. These activities and others have contributed to make the Massachusetts cancer program the pattern for cancer programs in this country and abroad.

Diagnostic cancer clinics are functioning in eighteen strategic points throughout the Commonwealth. At these clinics, persons with suspected cancer are examined and then returned to their physicians with a statement of whether a malignant tumor was found. In the early years of the program the majority of the patients came as the result of newspaper publicity, but at the present time nearly 90 per cent of them come on the advice of local physicians. Uniform records are kept in all eighteen clinics, and follow-up observation is maintained from the diagnosis of cancer until death. The long-term follow-up study of more than 20,000 patients with cancer is one of the unique features of the program. Of the cancer patients who were seen in 1927, 2 per cent are lost, 11 per cent are still alive, and the remainder are dead.

At the Tumor Diagnosis Laboratory tissue is examined as a free service to any physician in the Commonwealth. The increasing number of specimens submitted by the profession is an indication of the value of this service.

The dissemination of information regarding cancer has been an integral part of the Massachusetts

cancer program. In a nation-wide Gallup Poll held in 1939, only about half the persons interviewed believed that cancer was curable. A few years later, a similar result was found to exist in several Massachusetts cities. Within the past year, professional surveyors visited seven Massachusetts cities, including some of those surveyed earlier, and found that approximately 75 per cent of the people were aware of the curability of cancer. The educational work of the Department of Public Health is done mainly through committees in local communities striving to furnish information through public meetings, distribution of pamphlets, school programs and other means. Recently, the educational program has become a joint effort of the Department of Public Health and the American Cancer Society, Massachusetts Division, Incorporated. These two organizations, working together, should accelerate cancer education.

Throughout the period of the program, statistical studies have been made to measure improvements, to ascertain weaknesses, to evaluate clinic procedures and to determine factors dealing with the etiology of the disease. Among the more recent studies is one to determine the practicability of furnishing the Papanicolaou diagnostic test for vaginal smears to the entire medical profession. This study, financed by the Commonwealth Fund, is now in its third year, and although the study will not be completed for three more years, a few cases have been found in which a positive vaginal smear was the only indication of a uterine cancer. Another important study that has been completed recently deals with the changing cancer death rate, giving consideration to each site separately. Whereas for some years it was noted that there was a downward trend in cancer among women and that this trend occurred in Massachusetts earlier than in other parts of the country, the behavior of the trends for individual sites of cancer have been studied only recently. Even though the general trend of the cancer death rate for women is downward, certain sites, such as the lung, pharynx and ovary, show upward trends. The downward trends for cancer of the skin, mouth, stomach, uterus and perhaps breast are sufficiently great to influence the trend of the total cancer rate for females, but the downward trend

for mouth, skin and stomach among males is not sufficiently great to offset the sites with upward trends.

At the Fourth International Cancer Congress, held in St. Louis, the Department of Public Health reported on an interesting finding about half the women with cancer of the cervix had been married under the age of twenty, contrasted with a rate of about 18 per cent of early marriages in the general population. A large part of the paper was devoted to a discussion of this phenomenon.

The fourth part of the program is hospitalization. This has been so admirably discussed by Dr. Parker that little more need be added, except to decry the fact that many empty beds are to be found in this institution, owing to a lack of personnel. With the great demand of cancer patients and with the present limitation of facilities in general hospitals, it seems deplorable that less than a third of the beds in Pondville are being used. Every effort should be made to assist the superintendent and the staff in their effort to excel the prewar status of this hospital.

---

#### SANDERS COLLEGE

The third postgraduate lecture course, presented by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health in Sanders Theater, Cambridge, completed its annual term on May 5. The statistics here presented well justify the term "Sanders College" that has been applied to the course.

Between March 8 and May 5 ninety-six lectures were given in eighteen sessions. The total registration exceeded 1300, over a hundred more than in 1947, the gross attendance was 7400, with an average of 411 at each session. The sessions on allergy and psychiatry, the least well attended, drew each an audience of approximately 250 "students." A crowd of 850 thronged the sessions on cardiovascular diseases.

Congratulations are due to the Committee on Postgraduate Instruction, which arranged the program, as well as to the Hub of the Universe, where an indifference to learning can hardly be said to have manifested itself.

## MEDICOLEGAL ABSTRACT

**Liability for Malpractice—Duty of physician to explain cause of injury occurring during treatment** Many doctors have had the experience of a patient dying or being injured under circumstances that according to the ordinary course of events suggest that the doctor was negligent. He may be able to account for his own conduct and feel sure that it was proper even though he cannot explain how the injury occurred. A recent California decision makes it seem prudent for him to do whatever he can to determine the cause of the injury lest he be held responsible.

In an earlier California case (*Ybarra v Spangard*), in which the court, disposing of a contention that a plaintiff could not recover when he failed to show more than that after an appendectomy he had awakened with a painful shoulder, which subsequently resulted in an atrophied and paralyzed arm, stated

We merely hold that where a plaintiff received unusual injuries while unconscious and in the course of medical treatment all those defendants who had any control over his body or the instrumentalities which might have caused the injuries may properly be called upon to meet the inference of negligence by giving an explanation of their conduct.

This holding was based upon what is referred to as the doctrine of *Res ipsa loquitur*; that negligence is presumed when a plaintiff is injured by an instrumentality entirely within the defendant's control under circumstances that would not ordinarily arise unless someone had been negligent. The more recent California case clarifies the extent to which the defendants must go in making an explanation of their conduct under such circumstances.

A surgeon planned to remove a wart from a patient's nose after anesthetizing the patient with a nonexplosive gas, and then to remove the tonsils under ether anesthesia. The patient was completely anesthetized with nitrous oxide and oxygen, and the wart was removed with an electric needle. After the surgeon had finished removing the wart and was cauterizing the wound with the electric needle there was a "flash" and a "pop" about 6 inches above the patient's face. As a result of this accident the patient suffered contusions to the left cheek and left eye, bled profusely from the nose and mouth and was hospitalized for fifteen days. The doctor testified that at the time of the "flash" and "pop" the nitrous oxide and oxygen had been turned off and that the ether had not yet been turned on, that to give ether would have required the switching of the apparatus, and that the apparatus had not been switched. The doctor described in detail what he was doing before and at the time of the accident. However, neither the doctor nor the anesthetist could ac-

count—and neither attempted to account—for the "flash" and the "pop" that caused the injuries. The director of the anesthetic department of the defendant's hospital was called as a witness by the surgeon. He qualified as an expert on anesthesia, and when asked his opinion as to the cause of the "flash" and the "pop," he made the following statement:

I think that the strongest possibility From the information, I suspect My opinion would be, one probable likelihood would be, from contaminating substance in one of the tanks, some foreign substance

The nurse in charge of surgery testified that the breathing tube leading from the container to the patient's face had been properly washed with soap and water immediately before its use. The expert on anesthesia admitted that it was possible for a chemical laboratory to test nitrous oxide to determine if it were contaminated. It did not appear whether the defendants had made such a test of the nitrous oxide remaining after the operation. The jury rendered a verdict in favor of all the defendants.

On appeal the plaintiff contended that the jury should have been directed to find for her, and the upper court reversed the judgment and ordered a new trial, saying

The showing here goes farther than the establishment of a mere prima facie case under the doctrine of *res ipsa loquitur*. Not only is there a prima facie showing that the accident is one which in the ordinary course of events would not have happened if defendants had used due care but the defendants themselves have established the "possibility" or "probability" that they used an impure and, under the circumstances, dangerous anesthetizing agent. That agent, the nitrous oxide, was at all times concerned in the exclusive possession and control of defendants. If such nitrous oxide was not impure, it was in the power of defendants to prove the fact, if it was impure, as their evidence suggests, then the burden was on them to account for the impurity. The defendants offered to prove neither that the gas was pure nor that they were not responsible for its impurity. We are constrained to the conclusion that in a *res ipsa loquitur* case where, in addition to the prima facie showing of negligence, it is admitted or appears without dispute that the defendant has it in his power to produce substantial evidence material to the issue of negligence but fails to do so, it must be presumed that such evidence, if produced, would have been adverse to defendant, and under such circumstances the evidence is insufficient to support a verdict for the defendant and plaintiff is entitled to a directed verdict.

This is not to say that a defendant in a *res ipsa loquitur* case has the burden of proving himself free from negligence. It is not to say that a defendant must in every such case produce evidence of the actual cause of the accident. It is not to say that the question of the sufficiency of a defendant's explanation—or, if he cannot explain, the sufficiency of his evidence of due care and of impossibility of explanation—is not ordinarily for the jury. The general principle is, as stated by this court in 1919 (*in denying a hearing in Bourguignon v Peninsular Ry Co*, 40 Cal App 689, 694-695 [181 P 669]) "that where the accident is of such a character that it speaks for itself, as it did in this case, the defendant will not be held blameless except upon a showing either (1) of a satisfactory explanation of the accident, that is, an affirmative showing of a definite cause for the accident, in which cause no element of negligence on the part of the defendant inheres, or (2) of such care in all possible respects

as necessarily to lead to the conclusion that the accident could not have happened from want of care but must have been due to some unpreventable cause although the exact cause is unknown. In the latter case, inasmuch as the process of reasoning is one of exclusion the care shown must be satisfactory in the sense that it covers all causes which due care on the part of the defendant might have prevented."

"The defendants have not met either test above stated. They did not show a definite cause for the accident unless it was the use by them of an impure or contaminated anesthetizing agent. Such definite cause is not shown to possess no element of negligence on their part although evidence material to this issue was available to them. And in respect to an exclusionary showing as has been pointed out above the evidence fails in several respects to support a conclusion that the accident could not have happened from want of care. It fails in this regard not because of any showing of impossibility of proof but rather, because defendants having the ability to produce it chose not to do so. It is therefore apparent that upon any reasonable view of the record and giving effect to the rules of law hereinabove discussed the verdict of the defendants cannot be sustained.

In a vigorous dissent by three of the seven justices, it was stated

Under the doctrine of *res ipsa loquitur* the majority opinion in effect imposes upon a defendant even more than the burden of proving that he was not negligent. It imposes the burden of proving the actual cause of the accident, for that is the only practical way under the opinion that defendants can show that they were free from fault. The imposition of such a burden necessarily involves the adoption of a rule on grounds of policy that persons in attendance during an operation must explain not only their own conduct, but the conduct of any other person, such as a manufacturer of anesthetics, who might conceivably be responsible for the accident, as well as the forces of nature that brought it about. Such a rule would impose upon doctors, nurses, and members of hospital staffs absolute liability for unusual accidents that they cannot explain and might discourage their attending operations. A person about to undergo an operation is generally aware that there may be unforeseeable dangers incident thereto. He is entitled to an explanation of the conduct of the persons attending the operation, but he cannot reasonably expect them to be insurers of his safety.

Under the majority opinion the defendants would not have to prove the cause of the injury if they showed that it had not been caused by anything that due care on their part might have prevented. However, it is difficult to determine from the majority opinion in what respect the majority considered the defendant doctors negligent. The court objected to their failure to produce evidence that they might have produced regarding the cause of the injury, but the evidence seemed to refer to possible negligence on the part of the manufacturers of the nitrous oxide or on the part of the hospital in its manner of storing it.

These details of evidence have no direct bearing on other cases involving different facts, but the prudence of determining the actual cause of an injury occurring under circumstances that otherwise suggest negligence on the part of the doctor is plainly indicated. (*Dierman v Providence Hospital, California Advance Reports* 31 A. C. No. 5, January 9, 1948, *revising* 79 A. C. 374.)

## MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH CONTAMINATED AMPOULES IN CIRCULATION

A communication has been received from the Federal Food and Drug Administration to the effect that three codes of Obeto Ampuls, manufactured by Ziegler Pharmacal Company, Buffalo, New York, have been found to contain viable yeast or bacteria. The known questionable code numbers are

7436

7275

7085

Other codes are now being checked

It is believed that this product has gone directly to physicians. If physicians have in stock any ampoules bearing the three code numbers referred to above, they are requested to return all unused stocks to the manufacturer immediately.

If it is subsequently determined that other codes of this product have been found to be contaminated, physicians will be advised accordingly.

## COMMUNICABLE DISEASES IN MASSACHUSETTS FOR APRIL 1948

DISEASE*	RÉSULTÉ		
	APRIL 1948	APRIL 1947	SEVEN YEAR MEDIAN

\*Four year median.

†Six year median.

### COMMENT

Diseases with incidence above the seven year median are chicken pox, diphtheria, bacillary dysentery, measles, mumps and salmonellosis.

Diseases with incidence below the seven-year median are German measles, lobar pneumonia, scarlet fever and whooping cough.

Diphtheria has shown a lower incidence six other times during April. Constant effort toward prevention is still needed. Mumps shows the highest incidence for April since 1915. Measles shows the fourth highest April incidence. Whooping cough is at the lowest level for April since 1915.

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Athol 1, Boston, 9, Hanover 1, Haverhill 1, Lowell 1, Natick 1, Revere 1, Waltham 2, Weymouth 1, total 18.

Dysentery, bacillary, was reported from Worcester, 12, total, 12  
 Encephalitis, infectious, was reported from Cambridge, 1, Milton, 1, total, 2  
 Malaria was reported from Boston, 1, Braintree, 1, Malden, 1, total, 3  
 Meningitis, meningococcal, was reported from Dracut, 1, Ware, 1, total, 2  
 Meningitis, Pfeiffer-bacillus, was reported from Rockport, 1, total, 1  
 Meningitis, pneumococcal, was reported from Framingham, 1, Somerville, 1, total, 2  
 Meningitis, other forms, was reported from Quincy, 1, total, 1  
 Meningitis, undetermined, was reported from Haverhill, 1, Melrose, 1, Wakefield, 1, Waltham, 1, total, 4  
 Salmonellosis was reported from Attleboro, 1, Beverly, 2, Boston, 2, Brockton, 1, Holyoke, 2, Lawrence, 1, Millbury, 1, Natick, 2, Peabody, 1, Salem, 2, Worcester, 1, total, 16  
 Septic sore throat was reported from Attleboro, 1, Boston, 4, Brockton, 1, Cambridge, 1, Dartmouth, 1, Greenfield, 1, Medford, 1, Milton, 1, total, 11  
 Trichinosis was reported from Fall River, 1, Hanover, 3, Pembroke, 1, total, 5  
 Typhoid fever was reported from Boston, 2, New Bedford, 1, total, 3  
 Undulant fever was reported from Boston, 1, Weston, 1, Weymouth, 1, total, 3

## MISCELLANY

### NEW VETERANS HOSPITAL SITE

Acquisition of a new 15-acre site in Boston for a thousand-bed Veterans Administration general medical and surgical hospital has been approved by President Truman and the Federal Board of Hospitalization

This tract of land, in Jamaica Plain, is bounded by Heath Street, South Huntington Avenue, Kenney Street and the Jefferson Public School playground

### BLUE SHIELD EXTENSION

The House of Delegates of the Connecticut State Medical Society has voted to establish a prepayment medical-care plan patterned after Blue Shield in Massachusetts

Medical service plans have also been established recently in Minnesota and in Chicago, and South Carolina has passed an enabling act permitting the formation of a Blue Shield type of prepayment plan in that state.

## CORRESPONDENCE

### SALT-FREE BREAD

*To the Editor* The increasing use of sodium-poor diets for patients with cardiovascular disease raises the problem of finding a baker who will prepare salt-free bread for the use of such patients. I have found Albert Duplain, of 61 Albion Street, Boston, to be most co-operative in making up batches of French-type bread without salt or shortening. No doubt other bakers will show similar willingness to make salt-free bread, although the limited demand will not offer them much financial incentive.

ROBERT W. BUCK, M.D.

5 Bay State Road  
 Boston 15

## NOTICES

### ANNOUNCEMENT

Dr James A. McLaughlin, of Marshfield, announces the opening of an office at 17 Leyden Street, Plymouth, for the practice of internal medicine.

## JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston  
 Lecture Hall, 9-10 a.m.

### MEDICAL CONFERENCE PROGRAM

Wednesday, June 9 — Further Observations in Hemolytic Anemia. Dr. William Dameshek.

Friday, June 11 — Histochemical Problems in Biology and Medicine. Dr. Edward W. Dempsey.

Wednesday, June 16 — Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon.

Friday, June 18 — Cardiospasm. Dr. Franz J. Ingelfinger.

Wednesday, June 23 — Myelography. Dr. Samuel Blank.

Friday, June 25 — The Treatment of Migraine. Dr. John R. Graham.

Wednesday, June 30 — Experimental Studies on the Restoration of the Circulation. Dr. Allan D. Callow.

On Tuesday and Thursday mornings from 9 to 10, Dr. S. J. Thannhauser will give medical clinics on hospital cases. On the second and fourth Friday afternoons of each month, therapeutic conferences will be held from 2 to 4 with round-table discussion. Dr. R. P. McCombs, moderator. Dr. Merrill Sosman will conduct x-ray conferences from 4 to 6. On Saturday mornings from 9 to 10 clinics will be given by Dr. William Dameshek. Medical rounds are conducted each weekday except Saturday by members of the staff from 12 to 1.

All exercises are open to the medical profession.

## NEW ENGLAND PEDIATRIC SOCIETY

The spring meeting of the New England Pediatric Society will be held in New Haven, Connecticut, on Wednesday, June 9.

### PROGRAM

*At New Haven Hospital (789 Howard Avenue)*

12 m. to 1 p.m. Pediatric Conference

1 to 2 p.m. Luncheon

2 to 4:30 p.m. Scientific Program

*At New Haven Medical Association (364 Whitney Avenue)*

5 to 6 p.m. Social Hour

6 p.m. Dinner

7 p.m. Multiple Birth in Colonial Times. Dr. Ernest J. Caulfield, of Hartford, Connecticut.

## AMERICAN ASSOCIATION OF MEDICAL MILK COMMISSIONS, INC.

A meeting of the American Association of Medical Milk Commissions, Inc., will be held at the Avalon Hotel, Waukegan, Wisconsin, from June 18 to 21. Dr. Tom D. Spies, of Birmingham, Alabama, will be the principal speaker at the scientific meeting on June 19.

## SOCIETY MEETINGS AND CONFERENCES

### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JUNE 10

#### FRIDAY, JUNE 11

\*9:00-10:00 a.m. Histochemical Problems in Biology and Medicine. Dr. Edward W. Dempsey. Joseph H. Pratt Diagnostic Hospital.

\*10:00 a.m.-12:00 m. Medical Staff Rounds. Peter Bent Brigham Hospital.

12:00 m.-1:00 p.m. Clinicopathological Conference (Boston Diagnostic Hospital). Joseph H. Pratt Diagnostic Hospital.

#### MONDAY, JUNE 14

\*12:00 m. Clinicopathological Conference. Margaret Jewett Hall. Mt. Auburn Hospital, Cambridge.

#### TUESDAY, JUNE 15

\*12:00 m. X-ray Conference. Margaret Jewett Hall. Mt. Auburn Hospital, Cambridge.

\*12:15-1:15 p.m. Clinicoradiogenetological Conference. Peter Bent Brigham Hospital.

(Notices concluded on page xiii)

## NOTICES (Concluded from page 820)

\*1:30-2:30 p.m. Pediatric Rounds. Barnham Memorial Hospital for Children Massachusetts General Hospital.

## Three Mighty Important Ideas

*Maybe you read, where a great encyclopedia has sorted all basic ideas into a few select groups Under the letter "T" they have*

### Temperance—Truth—Tyranny

Sounds like a funny combination And to philosophize a little, notice that Truth is in the center—between Tyranny and Temperance

*Now and then you hear folks criticize temperate people who enjoy a moderate glass of beer who talk about "two beers" getting someone into trouble, and claim "There ought to be a law!"*

Then Truth steps in between, and points out that two beers never got anybody into trouble—and that somebody's trying to distort the facts No, there shouldn't be a law—there should be Truth

*From where I sit, those ideas are arranged just right Temperance on one side, Tyranny on the other—and Truth in the middle—seeing that Tyranny never encroaches upon Temperance*

## THE SHATTUCK LECTURE

### SURGERY IN THE AGED\*

C STUART WELCH, M.D.†

BOSTON

THE honor of delivering the fifty-ninth Shattuck Lecture has been given me, I take it, because of my recent appointment to the professorship of surgery in Tufts College Medical School. This pleasant and honorable task is a great responsibility, and I approach it realizing the difficulty I shall have in upholding the high tradition left by the long line of distinguished physicians who have preceded me.<sup>1</sup> The subject for this evening is surgery in the aged, a topic that to some degree will give consideration to an aspect of the diseases of the inhabitants of the Commonwealth in keeping with the suggestion of Dr. George Cheyne Shattuck, whose bequest founded this lecture.<sup>2</sup> The substantial yearly increase in the proportion of elderly people in the population of this country that has been going on since Dr. Shattuck's time reflects the accomplishments of medical people as they have turned their efforts to science and to practice. Medicine may take great credit among the biologic sciences, for the reduction in infant mortality and the control of infectious diseases have allowed more of the newborn to reach mature age.<sup>3</sup> These are the principal factors responsible for more and more people entering the aged group. Data from the annual report on vital statistics of Massachusetts reveal that one hundred years ago 80 per cent of deaths occurred in persons before they had reached their fortieth birthday. Today only 14 per cent of deaths are recorded in this relatively young group of people (Fig. 1). During the same period we have not made commensurate strides in the control of the diseases of maturity in later life. We are struggling with these problems now. The man beyond seventy years of age today is probably no better a physical organism than his counterpart a hundred years ago, but there is no doubt that much more effective treatment for his ills is available today than

existed in 1848. New England ranks first among the various regions of this country as the home of the aged, and Massachusetts is second only to the state of Vermont in New England for its high proportion of old inhabitants. Its longer establishment with an attending decrease in the number of young foreign and domestic settlers is beginning to demonstrate a trend toward a fixation of its population, with a concomitant increase in the aged group. The medical problems of the aged,

FIGURE 1. Percentage of Total Deaths Occurring in Persons under the Age of Forty Years in Massachusetts

therefore, have particular significance for the members of the Society, and since we face, according to predictions, a doubling of our aged population by 1980, the whole subject of geriatrics should assume increasing importance. Data from the census of the United States indicate that Massachusetts has approximately nine times as many people who have reached the age of fifty as it had in 1850. These 1,036,104 persons make up almost a quarter of our population (Fig. 2). Population increase alone does not account for this total figure, for there has also been a constant increase

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 25, 1948.

in the number of the elderly per one hundred persons in this state (Fig 3) Looking at the other side of the picture, we find that 42.3 per cent of our people were twenty years of age or younger in 1840 whereas only 30.7 per cent were found to be in this age group in 1940. Of greatest signifi-

FIGURE 2 Number of Persons Fifty Years or Older in Massachusetts

cance to our discussion of surgery is the fact that today 5 per cent of the population of Massachusetts is composed of men and women who have reached or passed their three score years and ten, a proportion twice that which obtained in the year 1850. The female of the species is more numer-

FIGURE 3 Age Distribution of Massachusetts Population

ous among the aged, and she has, each year, greater life expectancy and may expect a lower mortality from all diseases.<sup>4</sup> The aging process varies in individuals, and although a minimum of wear and tear is helpful in supporting a long and useful life, heredity probably is the greatest single factor that

works for or against a hale and hearty longevity.<sup>5</sup> It is impossible to set a standard for the beginning of old age, for each individual requires separate appraisal. The age of sixty-five is frequently used as the base line for the presentation of medical and surgical geriatric problems, but I am in agreement with Brooks<sup>6</sup> that the inclusion of persons aged sixty-five to seventy in these studies brings into the picture too large a number of patients who have only recently passed the average duration of life. As a matter of fact, in statistical studies of surgical patients that include those aged sixty-five and beyond, one finds that half or more have not reached the age of seventy but are in the age range of sixty-five to sixty-nine.<sup>7</sup> The age of seventy, therefore, seems the more critical one for presentation of the difficulties that attend surgery in patients of advanced years. I shall attempt to present a general survey of the surgical problems as they are met in this aged group. In addition, I wish to emphasize the encouraging side of the story by commenting on the progress made in surgical practice during recent years, which has brought unexpected benefit to old people and added useful years to their lives.

#### OPERATIVE SURGERY

As we review the progress made on all sides in medicine and surgery during the last twenty-five years, it would be small wonder if surgeons had not gradually accepted an increasing number of elderly patients for major surgery. With this experience has come surprising satisfaction to surgeons, who have had the pleasure of observing how well many aged patients withstand even the newer and more radical operative procedures as they are introduced. Although it is true that mortality rates are somewhat higher among these patients and much depends upon whether an emergency situation is to be dealt with, the procedures are not so prohibitive as we used to believe them to be. Numerous accounts in the literature attest to these facts.<sup>8-14</sup>

This changing scene in surgery is well demonstrated in the history of the surgical treatment of aged patients at the Carney Hospital. In 1900 only 15 persons of seventy years of age or more were operated upon in this institution, of whom over half had operations on the eyes, no abdominal surgery was done. Twenty-five years later 28 patients, or nearly twice as many as in the year 1900, were operated upon, and at that time a few more major procedures were carried out. Several hernioplasties, amputations of the leg and mastectomy procedures were performed. No resections of the stomach or colon, however, were undertaken. In 1947, not quite 25 years later again, 128 patients seventy years of age or over underwent surgery, and among them 41 had abdominal operations performed. Although it is true that the

hospital admissions had trebled at the Carney Hospital in the forty-seven years since 1900, it is obvious that the number of aged patients subjected to operations had increased out of proportion to the larger census and that more major procedures are now being undertaken. Surgical practice varies in different institutions depending upon their size, location and institutional developments in special fields. The operative work done by my colleagues at the Carney Hospital during the last five years had been generally illustrative of the problems commonly met in geriatric surgery, and I shall present their experiences to give a cross-

agency operation. Bronchopneumonia was recorded as the cause of death in 9 patients, infection in 7, massive pulmonary embolism in 4, and cerebral hemorrhage in 3. Four patients died of surgical shock. Not only is the circulatory mechanism easily embarrassed in the aged patient with peritonitis, pneumonia and sepsis but also sudden cardiac and peripheral arterial accidents are unfortunately common. Cardiovascular complications represent the *blitz* of surgery in the aged.

The average age of all patients in the series was found to be seventy-four years. In the fields of

\*Carney Hospital series.

section picture of the surgical requirements of elderly people.

In the five-year period 1943 through 1947, 609 operations were performed on 542 patients who had reached or passed their seventieth birthday in this institution of mixed public and private constituency. These data are presented in Table 1 and classified according to the type of operation that the patients underwent. The larger number of operations than patients is accounted for by stage procedures, particularly in the operations of prostatectomy and resection of the colon. More patients were subjected to abdominal surgery, although more operations were performed in the urologic field. Sixty-two of these 542 patients died in the hospital after operation, representing a total mortality of 11.4 per cent. In Table 1 the mortality rates for patients and operative procedures are separately recorded. Twenty-three patients died of cardiac failure, with renal complication in some cases, as might have been expected in this age group. Twelve patients died of peritonitis, among the group of 29 who succumbed after abdominal surgery, many of the deaths from peritonitis were among patients who required

orthopedic and vascular surgery, the average age of patients was seventy-seven years—higher than that in the other specialties. Eighty-five persons (15.7 per cent of the total) were eighty years of age or older, and 5 were in their nineties. The urologists had to deal with the larger number of patients beyond the age of eighty. Two hundred and eighty-four were females, and 258 were males. The surgery required by elderly people varies considerably from that of the young or middle-aged patient as Brooks<sup>6</sup> has pointed out. Approximately two thirds of them in our series, however, required abdominal, urologic or ophthalmologic surgery or surgery for diseases of the peripheral vessels. The major problems incurring higher mortality rates require separate discussion, for by a study of this group we may learn to recognize the obligations we face in avoiding disastrous situations that attend procrastination in our care of the aged.

#### Cancer

Twenty-eight per cent of the patients in this series were operated upon because of malignant disease. All had carcinoma except 2—1 patient of the bone, and another.

the uterus. In Table 2, the sites of these lesions are recorded. Carcinoma of the gastrointestinal tract was most commonly encountered and represented the most important division of the work in abdominal surgery. The second largest incidence of cancer was found in the patients requiring urologic surgery. Cancer of the prostate in male patients was the principal cause of a high incidence of 19.6 per cent among the elderly patients treated by the urologists. A fairly substantial number of patients have superficial or palpable lesions. Epithelioma of the face and cancer of the lip are fortunately

TABLE 2 *Cancer among 153 Patients Seventy Years of Age or Over \**

\*Carney Hospital series

easily detected and treated, and with the smaller risk entailed in the necessary operations there is little excuse for delay in proper treatment. There were 26 patients with cancer of the breast who were operated upon without any deaths in the group. Primary radical mastectomy was performed in 19, 2 additional patients had secondary axillary dissections after simple mastectomy had

TABLE 3 *Cancer Death Rates in Massachusetts for Persons Seventy Years of Age or Over*

YEAR	POPULATION	DEATHS FROM CANCER	RATE PER 100,000 DEATHS FROM CANCER
1900	84,751	476	562
1920	121,926	1269	1041
1940	216,494	2695	1245
1945	226,299	3067	1355

been done previously. In 5 cases the surgeon elected to perform simple mastectomy alone. As a general rule, it is safe to say that in almost all patients, radical mastectomy can be done with very low risk.

The cancer problem in the aged patient is becoming increasingly important. Among the causes of death for 1946 in the report on vital statistics for Massachusetts, cancer ranked second to the circulatory group in importance for persons of seventy years of age and beyond. In Table 3 the cancer death rates in Massachusetts for these persons

are recorded for several years. In 1900 there were 562 per 100,000 deaths attributable to cancer in patients seventy years of age or over. This figure had risen in 1940 to 1245 per 100,000 and had increased to 1355 for the year 1945. Thirty-nine per cent of all deaths from cancer in this state occurred among patients seventy years of age or older during 1946. Early diagnosis with adequate prompt treatment is due to the older patient as well as the younger. There has been a tendency among physicians to allow even easily treated superficial and palpable cancer to proceed to an advanced stage without treatment on the basis of the faulty reasoning that death from another cause might easily overtake the very old person before he succumbs to cancer. Almost a third (29.4 per cent) of patients with cancer in the Carney Hospital series of aged patients had superficial or palpable lesions. These were treated by surgery without incurring any mortality. Life-expectancy tables for the aged group are illuminating and should give the physician pause before he makes purely speculative decisions about these matters for his patients. Persons who live to seventy are in a group whose life expectancy is approximately nine years, and those aged eighty have an expectancy of about five years of life.<sup>6</sup>

It was not a long while ago that patients with intra-abdominal cancer were denied operation by the surgeon on the basis of advanced age alone. Now this time has passed. Certainly, when surgery is the only or best treatment for a given malignant lesion, the risk in relation to the patient's disease and his general health should assume sole importance in deciding for operation or the procedure best adapted to the situation. With the inevitability of death from cancer, fairly wide chances are often justifiable. Fortunately, the increasing demonstration of reasonable safety in operative surgery today, as well as the encouraging evidence that patients with cancer are seeking medical advice more promptly,<sup>18</sup> has given surgeons sufficient experience in the treatment of the aged patient with cancer to establish an imposing evidence that risks have been overestimated in the past. In addition it is all too true that the question of the evaluation of a patient's status is difficult. Some patients judged to be poor risks do surprisingly well, on the other hand, it must be admitted that others with greater expectations have proved disappointing.

Some may ask whether or not the larger number of patients being successfully operated upon for cancer has not increased the life expectancy in the aged population and decreased the death rate among elderly patients. Certainly, it is the individual experience of all surgeons that the life expectancy of many of their patients has been improved and that some patients have been cured. The question is difficult to answer for a number

of reasons, the first of which is that cardiac and vascular diseases greatly outstrip cancer as a cause of death in the old. The field in cancer treatment, although substantial, is too small to make a great impression on vital statistics. Secondly, the increasing number of persons who now live to the age of seventy each year and go on to develop cancer produces an ever enlarging aged population dying of this disease. These factors tend to obscure the results of our efforts in treatment. In succeeding years, perhaps, some statistical evidence may reflect the results of effective cancer treatment among the aged.

### Abdominal Surgery

Abdominal operations were attended by a higher mortality than others in the Carney Hospital series of elderly patients. This finding is a constant one in all studies of surgery in the aged. Twenty-two and a half per cent of the 129 patients whose abdominal cavity was entered died during the post-operative period. The 140 operations performed on these 129 patients are listed in Table 4. The seriousness of the disease was the principal factor influencing increased mortality. The important categories of abdominal surgery in the aged are the management of cancer of the gastrointestinal tract, urgent abdominal operations for acute conditions and surgery for gallstones.

**Cancer of the gastrointestinal tract.** Thirty-nine and nine-tenths per cent of the patients undergoing abdominal surgery had cancer of the gastrointestinal tract. Of these 61 patients only 24, or approximately 40 per cent, were found to have resectable lesions. Advanced disease with metastases was an unfortunate finding. Patients with carcinoma of the colon were more frequently admitted to the hospital with intestinal obstruction, sometimes of long duration, requiring emergency decompression operations. Many of these patients did not survive. These complicating factors made operation particularly hazardous and account, to an important degree, for a higher mortality and lower resectability than obtains among younger patients. It is common knowledge that symptoms in elderly people are frequently neglected by themselves and their associates, and are interpreted as natural in the course of old age. Temporizing, delay in diagnosis and finally reluctance to suggest surgery are all too common errors on the part of the physician in his attendance on elderly patients. Early diagnosis in cancer of the colon not only offers a chance for cure but avoids the high mortality accompanying intestinal obstruction in the aged. The complaints of the elderly should be heeded and given as serious study and attention as those of younger persons. The operative mortality among the patients with cancer of the gastrointestinal tract in this series, including those who succumbed after emergency surgery

done for acute intestinal obstruction, was 29.5 per cent, and although this figure seems high, it represents a considerable improvement over the reported results of ten years ago. When carcinoma of the gastrointestinal tract in elderly persons can be treated by elective operation the mortality figures are substantially lower.<sup>12</sup>

An outstanding achievement in the surgery of cancer of the gastrointestinal tract has been the

\*Carney Hospital series.

†Total gastrectomy.

trans thoracic approach and resection for cancer of the esophagus and cardiac end of the stomach.<sup>13</sup> Cancer of the esophagus is a disease of the older age group. Sweet's<sup>14</sup> recent report of his experiences in performing esophageal resection with high intrathoracic esophagogastric anastomosis reveals that half his patients were sixty-five years of age or more and 5 patients were seventy or over. The results obtained in the surgical treatment of cancer of the esophagus not only are remarkable in themselves but also offer the most convincing evidence supporting a contention that advanced age is not at all an insurmountable obstacle to radical extirpative surgery for cancer.

**Urgent abdominal surgery.** Thirty-one of the 140 abdominal operations were done as emergency procedures. Intestinal obstruction was the diagnosis in three quarters of these patients and accounted for 10 of the 12 deaths in the group. Cutler,<sup>15</sup> in

his study on surgery among aged patients at the Goldwater Memorial Hospital in New York City, has reported a similar experience in patients requiring urgent surgery. That old people do not tolerate intestinal obstruction for many hours and that surgical intervention is accompanied by high mortality is the unfortunate experience of all those reporting on this subject.<sup>20</sup> Incarcerated or strangulated inguinal hernia was the cause of obstruction in more than a quarter of the patients with intestinal obstruction, and this fact alone should justify hernia repair by election in those patients whose histories indicate that incarceration has occurred in the past. Quigley<sup>21</sup> has shown that herniorrhaphy is a safe procedure in the aged patient,

TABLE 5 *Mortality in 65 Abdominal Operations Performed at a Time of Election on 57 Patients Seventy Years of Age or Over\**

TYPE OF OPERATION	NO. OF OPERATIONS	DEATHS IN HOSPITAL
Gastric (16 operations 3 deaths)		
Gastrostomy	4	1
Gastrojejunostomy for benign ulcer	2	0
Gastrojejunostomy for cancer	2	1
Gastric resection for benign ulcer	1	0
Gastric resection for neoplasms†	7	1
Biliary (13 operations 1 death)

†For cancer in 5 and for adenoma of the stomach in 2 cases

incurring small risk. Femoral hernia in the elderly female is very frequently unrecognized both by the patient and by the physician. A careful examination for small masses protruding from the femoral ring is a most important part of physical diagnosis in elderly women with obvious obstruction of the small intestine. Fortunately, strangulation of the bowel is infrequent with femoral hernia.<sup>22</sup> Acute appendicitis is rather rare among the aged, and, in our series, there were only 4 patients with this disease among 542. It is important to bear in mind that symptoms of appendicitis in the aged are insidious and that the disease is frequently advanced a few hours after the onset of pain. The majority of elderly patients are found to have gangrenous appendicitis or perforation at operation. Early operation is essential.<sup>23</sup> Perforation of a peptic ulcer is sometimes encountered even in the very old, and this disaster is often fatal.<sup>24</sup> In general, it is true that peritonitis is poorly tolerated in these patients. The treatment

of massive hemorrhage from gastric and duodenal ulcer is an equally important aspect of the peptic-ulcer problem in older persons. Since the publication of Allen and Benedict<sup>25</sup> in 1933 a great deal has been written to emphasize the fact that a higher mortality attends ulcer hemorrhage as age progresses.<sup>26</sup> Surgical intervention has been suggested and carried out sporadically.<sup>27, 28</sup> The relative merits of nonoperative and operative treatment for the very old patient have not been decided. Although surgery may prove to have a useful field in the immediate treatment of hemorrhage in some patients beyond the age of fifty, it is doubtful that operative intervention is the wise course in the very old since an extensive gastric resection is usually required for the control of bleeding involving high risk under these conditions. Co-operation between the physician and surgeon in the management of these patients, however, is most desirable, and recent advances in our present appreciation of the significance of blood loss and blood replacement in the management of patients with hemorrhage from ulcer has offered a better prognosis by nonoperative management than that obtained under the conditions of the older policy of starvation and dehydration.<sup>29</sup>

**Biliary surgery** Surgery of the biliary tract accounted for about a quarter of the abdominal operations in the Carney Hospital series (Table 4). The significant feature of biliary-tract surgery in the aged is that over half the patients are found to have complicated disease—common-duct stone, acute cholecystitis or cancer of the gall bladder. Often elderly patients have obstructive jaundice and in some cases jaundice has been allowed to exist for long periods of time. Quigley<sup>30</sup> has reported a mortality of 13 per cent for biliary surgery in patients aged sixty-five or over with gallstones and has clearly pointed out the increased morbidity and mortality that accompany surgery for this disease in the aged group as related to the complicating factors of acute cholecystitis and obstructive jaundice. The mortality for simple cholecystectomy done as an elective procedure is relatively low even in patients of advanced age. Glenn and Heuer<sup>31</sup> have stressed the importance of performing surgery of the biliary tract in the early decades of life to avoid the high mortality associated with emergency procedures for acute cholecystitis as age increases. The problem of advising surgery in patients with gallstones seems always to present a dilemma for the physician. It is difficult to make hard and fast rules but the facts about gallstones in the aged patient should be borne in mind at the time of decision in younger subjects with cholelithic disease.

**Elective abdominal surgery** When adequate preparation before operation is possible, there is, of course, greater safety for the patient, and morbidity is correspondingly less. In a separate con-

secutive series of 57 patients aged 70 years or more, upon whom we performed 65 abdominal operations electing the time and conditions for surgery, the mortality was found to be 15.6 per cent for patients and 13.8 per cent for operations (Table 5). These operations were done largely before the extensive use of chemotherapy and antibiotics. Surgery of the biliary tract carried the least risk. Operations on the stomach, colon and rectum were accompanied by approximately three times the risk of that for operations on the gall bladder and bile ducts for gallstones. Cancer of the stomach, with its known tendency to early metastasis and extension, probably offers the most serious operative surgical problem in the elderly patient if cancer of the pancreas and bile ducts is excluded. The operations of total gastrectomy, transthoracic esophagogastrectomy and partial gastrectomy done as a palliative procedure are understandably attended by higher mortality rates than extirpative operations for cancer of the colon and rectum. The nature and extent of the disease again seems to be the common denominator influencing the outcome for the patient.

### *Urologic Surgery*

The necessity of relieving urinary obstruction in the elderly male patient is the principal problem in urologic surgery. In addition to the treatment of benign prostatic hypertrophy, cancer of the prostate assumes greater importance as age progresses.<sup>22</sup> It is also true that a higher mortality rate may be expected in surgery for cancer of the prostate. Recently, castration and estrogen therapy have come to have a significant role in the disease and offer additional benefits for the old patient.<sup>23-25</sup> In general, progress in urologic practice has had a great deal to offer the elderly male patient. It is interesting to note that the urologic service at the Carney Hospital performed the largest number of operations although the number of patients upon whom the urologists operated was slightly less than that of the abdominal-surgery group. The total operative mortality was 9.4 per cent for 149 operations and 12.4 per cent among 113 patients. Many of these patients entered with acute urinary retention, and, indeed, some of the deaths occurred in those who succumbed after suprapubic cystostomy alone. It has been well established that prostatectomy can be done with reasonable safety today by any of the several techniques, and enormous improvements have been made in the preoperative, operative and postoperative care of patients with urinary-tract obstruction.

Before a period of ten years ago the mortality from the operation of prostatectomy throughout this country was in the neighborhood of 15 or 20 per cent, according to Cabot,<sup>26</sup> for patients of all ages. At the present time the mortality rates for the suprapubic, perineal or transurethral methods

of resection are probably in the neighborhood of 4 per cent or less,<sup>27, 28</sup> depending upon the selection of patients submitted to these procedures.

Without entering too far into the somewhat controversial field of prostatectomy technique, on which I am not qualified to speak, a survey of the literature indicates that two things have been especially valuable to urologists in including a larger number of elderly patients in the group for prostatectomy. The first of these is the marvelous safety of low spinal anesthesia in these operations. Small amounts of drug only need be given, anesthesia is of short duration, and recovery rapid. The second factor is the more universal use of the transurethral method of prostate resection in patients of uncertain risk who, fifteen or twenty years ago, might otherwise have been consigned to a catheter life or to permanent suprapubic cystostomy.<sup>29, 30</sup>

### *Ophthalmologic Surgery*

Surgery of the eye has been done on aged patients for many years, and perhaps the ophthalmologists should be considered pioneers in geriatric surgery. Ophthalmologic surgery was possible at an earlier date than other operative work because the hazard to life has been negligible in this field. There were 2 deaths among 67 patients operated on at the Carney Hospital, but neither was related to the surgical procedure and might have occurred in these patients at any time. Operations for cataract are highly successful,<sup>31</sup> and the surgical treatment of glaucoma has offered immeasurable comfort to many of these patients. Not only has eye surgery been a boon to the aged patient but also the alleviation of blindness very often relieves the family by converting a burdensome elderly person into a useful member of the household. In the Carney Hospital series, eye surgery ranked third in importance among aged patients.

### *Surgery for Peripheral Vascular Disease*

Fifty-four of the 542 patients in our group required operation for problems related to disease of the blood vessels of the lower extremities. About half these patients were treated for varicose veins or for thrombophlebitis by the various established ligation procedures. Prophylactic ligation of the deep leg veins for the prevention of thrombosis and embolism was not generally practiced. Ligation after evidence of deep phlebitis, however, was done in a number of patients.

Arteriosclerotic gangrene of the leg, sometimes complicated by diabetes, made up the most serious problem. Twenty-six patients required amputation of some portion of the extremity, and 23 of these underwent thigh amputation. Six patients (21.6 per cent) died after thigh amputation. This mortality rate represents a reduction from that which could have been achieved fifteen years ago in patients of this age. In addition to the many

new supportive measures that are applicable to all surgical patients, the control of sepsis by chemotherapy and antibiotics deserves special mention in the better results now obtained in patients with gangrene of the leg. The use of refrigeration before surgery and of refrigeration anesthesia as reported by O'Neil<sup>42</sup> and others<sup>43</sup> seems to have been a definite implement in reducing mortality in the hands of some surgeons. In the management of gangrene of the leg at the Carney Hospital, refrigeration anesthesia was not used extensively, but the control of infection and the adequate use of blood transfusions were found to be most important before and after operation. Low spinal anesthesia was employed almost exclusively. McKittrick<sup>44</sup> has shown that the use of penicillin and control of sepsis have made possible conservative transmetatarsal amputations in diabetic patients, some of whom, in former years, would have been subjected to major amputations. The outlook for patients with gangrene of the leg has immeasurably improved in the last few years.

### *Orthopedic Surgery*

We can all recall the disheartening picture presented by the large number of old men and women with fractured hips who crowded the surgical wards up until recent times, and although the problem of the fractured hip is still a very difficult one and far from solved, fewer patients die in the early period after fracture and many are quickly made ambulatory. Before the beginning of the extensive use of internal-fixation procedures, many of these patients with hip fracture rapidly succumbed from bronchopneumonia. Others developed huge decubitus ulcerations, which made them a great nursing problem and hindered their chance of recovery. At best, unsatisfactory treatment with indifferent results after a long hospital stay was the lot of those who survived. At the present time, the work of the orthopedic surgeon in the early operative treatment of femoral-neck and intertrochanteric fracture has greatly lowered the mortality, decreased morbidity and reduced the patient's hospital stay.<sup>45-48</sup> Low spinal anesthesia has proved to be the best choice for these procedures. Ideally, patients of advanced age, even those over eighty years of age, are operated upon within forty-eight hours of injury and rapidly made ambulant. The reduction in the incidence of decubitus ulceration has been one of the most important aspects of this program. It is true that the incidence of nonunion is high in the aged, but this fact does not influence the immediate value of the results now obtained. In the Carney Hospital series the average age of 37 patients undergoing bone and joint surgery was seventy-seven years, and fracture of the hip was the principal problem (Table 1).

Approximately a third (33.6 per cent) of the deaths in patients seventy years of age or over in Massachusetts during 1946 were accidental in nature, and accidents rank fourth in both sexes as a cause of death in elderly people. Prevention of home injuries might be a useful interest of the general practitioner as he visits his elderly patients, since hip fracture usually occurs in the home and its prevention is still worth more than all that our accomplishments have added to the treatment of this injury.

### *Gynecologic Surgery*

As age advances, the need for the gynecologist's services diminishes. Only 7.6 per cent of the operations in the Carney Hospital group of elderly patients were done for diseases of the female genital tract. Forty operations were performed, and 14 of these were carried out from below. Cancer in this group of patients, however, requires major operation, and the distressing condition of uterine prolapse is a major affliction for some elderly women. Fortunately, operations by the perineal route are well tolerated and accompanied by a low mortality.<sup>49</sup> There should be little hesitation in recommending surgery for herniation of the bladder or for other lesions resulting from relaxation of the pelvic floor in women of advanced age.<sup>50</sup>

### *Other Important Operative Procedures*

In the groups of operations classified as miscellaneous in Table 1 thyroidectomy for hyperthyroidism and dissections of cervical lymph nodes in the treatment of metastatic cancer require mention. Lahey<sup>51</sup> has called attention to the manifestations of hyperthyroidism in older patients.

Relief of pain by neurosurgical procedures has a larger field than might be indicated by the absence of these operations among the elderly patients in our series. The operation of prefrontal lobotomy, now under trial, may become especially useful in the aged group. Tic doloieux is not infrequently encountered in the aged, and the relief of persistent pain after herpes zoster, peculiar to these patients, also presents a need for operative neurosurgery. Operations for the removal of brain tumors in patients over seventy are seldom carried out, but with the risk of intracranial surgery becoming less, we may expect that neurosurgeons will recommend operation among this group more frequently in the future. A great deal will depend upon the status of the patient and his disease, but increased risks in this field might be justified if a few useful members of society can be made out of persons who otherwise look forward to a vegetative existence.

### ANESTHESIA

The passing of the epoch when anesthesia was by necessity performed as a side issue to surgery by the youngest hospital staff member as he began

his hospital training, or later as he launched into practice, marked a great advance in modern surgery. Progress in anesthesia required the recruitment of physicians whose interests were not divided. The firm establishment that this specialty now enjoys with its separate training program and attractive opportunities for its qualified men is sure to keep offering continued advantages for the patient. The increased requirements that surgeons have made on the anesthetist's skill and knowledge as they have extended extirpative surgery for cancer and invaded new areas continue to be a great stimulus to these new specialists.

There is considerable discursive literature on the subject of selection of anesthesia for the elderly patient.<sup>22, 23</sup> All the evidence seems to show that in the hands of expert anesthetists there is a place for almost all technics and agents if an individualization of the patient's requirements is carefully made. From the standpoint of the poor-risk patient, several tangible facts about anesthesia seem to stand out that might permit of generalization. The first of these is obvious — an experienced anesthetist is the first requisite for difficult surgery, not only is he needed in the selection and administration of the anesthetic but also he removes a great load of responsibility from the surgeon's shoulders in assuming the management of blood and fluid replacement during the course of the operation. During the early postoperative period he has much to offer in preventing and treating pulmonary complications.

Regarding the selection of anesthetic agents and technics for elderly patients, agreement exists among the majority of anesthetists to a reasonable degree although there cannot be said to be a unanimity of opinion about the generalization I shall make.

Regional nerve block and local infiltration have a field of usefulness but the extent to which these procedures can be put is limited by the operation required and by the experience of the administrator. Certain nerve-blocking procedures require great experience and practice for satisfactory execution, and very few anesthetists have mastered all of them. Low spinal anesthesia is agreed to be ideal for prostatic surgery, for gynecologic surgery performed from below and for amputations of the leg. The paralysis produced fortunately involves only a limited amount of the autonomic and somatic nervous system.<sup>24, 25</sup> High spinal anesthesia involving nerve paralysis of a larger part of both systems is attended by greater fluctuations in the blood pressure and often by depression of respirations. Cardiovascular changes are almost always present in elderly persons, and under these circumstances high spinal anesthesia is not the best choice. Inhalation anesthesia using cyclopropane or ether and the endotracheal tube has proved most satisfactory and safe for

old patients undergoing surgery of the upper abdomen in the opinion of many anesthetists. Intravenous anesthesia using pentothal sodium not only has its limitations of usefulness as a single agent, often requiring combination with others, but also, because of its depressant and toxic action in large doses, cannot be considered safe for the elderly patient.

The least strain that is put upon the patient during the whole surgical procedure, including the induction of anesthesia, the better for the elderly patient, whose limits of physiologic adjustment are confined to narrower ranges than those of younger persons. Reasonable speed without dangerous haste in the accomplishment of an operation likewise may lessen the burden on these patients since a long operating time has been found to be a factor influencing mortality.<sup>26</sup>

#### SURGICAL ADJUNCTS AND SAFEGUARDS

Bringing the elderly patients safely through major surgery has no specific formula. All measures found useful in the safe conduct of the adult surgical patient apply to the elderly, but must be intensified in their application. Wangensteen<sup>27</sup> points out that greater precision in the application of all measures in the preoperative period at operation and during the postoperative course is mandatory in the management for the very old patient who is a border-line risk. He rightly cautions us to avoid that allowance of latitude in our exactness which in the younger person does not turn the balance unfavorably. True also is his statement that seldom does the old patient suffer from one disease. The principal cause of death in old age is heart disease, and cardiac deaths and peripheral-vessel accidents account for more than half the fatalities in patients over the age of seventy. The aged patient comes to surgery with handicaps that cannot be greatly improved in the preoperative period, but must be heeded in the estimation of risk and in the management of the entire surgical performance. Cannon<sup>28</sup> has summarized the aged person's capacity in the following statement:

A survey of the chief agencies concerned in maintaining homeostasis of the acid base balance — lungs, blood vessels and heart — shows that as life proceeds to its later stages there is likely to be in each of these organs a narrowing of the capacity to adjust for special requirements. A routine existence within the limits of easy adaptation may continue indefinitely without revealing any weakness, but exposure to a stress which encroaches on the limits quickly discloses that they have become much restricted.

In the changing scene of surgery today we may point to certain stabilized adjuncts that have greatly influenced our good results and increased the width of the application of surgery to the aged. Of all these benefits, which have come in many forms such as chemotherapy in the preparation of the intestinal tract for operation, antibiotics

and chemotherapy in the treatment of infection and new anesthetic drugs and technics, none can compare, I believe, with the help that a safe procedure for blood transfusion has provided. The universal use to which this supportive measure has been put by the surgeon in the correction of severe anemia and the restoration of blood volume before surgery, as well as in the replacement of blood as it is shed during operation, has perhaps no peer in supporting surgical practice. The newer studies of Lyons<sup>59</sup> have shown us particularly the importance of blood-volume estimations as an index for estimating the blood-replacement needs in patients if they are to be optimally prepared to withstand long and difficult surgical procedures. Elderly patients with cancer of the gastrointestinal tract exhibiting weight loss have a reduced blood volume, and under these conditions are more vulnerable to surgical shock at operation and less well prepared to meet the postoperative period. Indications for adequate preoperative transfusion therapy require blood-volume studies, since accurate information from the blood-cell count, hemoglobin value, hematocrit reading and plasma protein determinations are misleading and do not estimate this factor of the quantity of available circulating mass. Wangenstein's<sup>60</sup> practice of accurately measuring blood loss during operation with quantitative replacement represents a particular refinement of supportive treatment by blood transfusion. Clinical estimations have proved satisfactory in the hands of most groups.

The nutritional deficiencies of elderly patients with cancer of the gastrointestinal tract have been elaborately studied by Varco.<sup>61</sup> Experimental and clinical investigation has related hypoproteinemia and vitamin deficiency to poor tissue healing.<sup>62-65</sup> The application of the knowledge to practice probably has not kept pace with these developments. The dietary management of patients who have sustained great loss of weight during their disease has been carefully described by Wangenstein<sup>60</sup> and by Varco,<sup>61</sup> but few of us have had the patience to carry out these details. Rapid preparation of depleted patients by adequate blood transfusion is the common practice, and may be the better choice under most circumstances since preparation time is not unlimited.

Adequate hydration is necessary, but too often in the elderly person overhydration is practiced. Excessive sodium administration can, in the presence of a weak heart, actually precipitate failure that may be fatal and probably represents an insufficiently appreciated cause of death in the postoperative period.<sup>66</sup> It is not a bad practice to run the elderly patient a little short on sodium chloride.

One of the most difficult situations in the elderly patient is that of pressure necrosis of the skin, with its resulting bedsores.<sup>66</sup> Its treatment is difficult, and its prevention our best hope. Constant mov-

ing of the patient as soon as he becomes confined to bed, with the alleviation of pressure on the areas that usually bear weight in the dorsal decubitus position, is the best insurance against this complication.

I have mentioned prophylaxis directed at decreasing the incidence of thrombophlebitis and pulmonary embolism by ligation of the deep veins of the leg now widely practiced since the demonstration by Homans<sup>67</sup> of its value in the prevention of embolism. Allen and his associates<sup>68, 69</sup> at the Massachusetts General Hospital are convinced of the efficacy of this practice carried out under the conditions of their routine and report a reduction in the incidence of fatal embolism among their patients. Good results in the control of this complication have also been reported by those who have used anticoagulants, in the form of either dicumarol<sup>70, 71</sup> or heparin.<sup>72, 73</sup> The majority of surgeons today, however, pursue what would seem to be a middle course program tending to rely on early ambulation and exercise as a preventive measure, and daily examination of the legs for detection of thrombophlebitis in the deep veins. Anticoagulant therapy and vein ligations are then reserved for treatment. That the answer to this problem remains to be solved, all will agree.<sup>74</sup> In the elderly patient, the known higher incidence of fatal embolism, however, makes it mandatory that some program be adopted, for loss of life from embolism has come to be considered in many quarters a surgical error.

Last of all, but not least, the long-term training programs in surgery conducted in our teaching hospitals offer an experienced full-time resident staff immediately available for the necessary vigilant care of patients whose survival may depend on special knowledge promptly applied at a critical time. In addition, each year for many years met have been moving out from these centers to community practice where they are on the scene to answer the surgical needs of our population. If no other country has surgery been taught so extensively by its preceptors, and decentralization of this specialty has moved ahead rapidly, making surgery of a high order available to a larger number of people.

#### SUMMARY

Five per cent of the population of the Commonwealth of Massachusetts is composed of men and women who have reached or passed the age of seventy years. Operative surgery in patients beyond the age of seventy has been demonstrated in the experience of recent years to be relatively safe. The yearly increase in the elderly population in this country indicates that we may expect a larger requirement for surgery among the aged as time goes on. The recognized higher surgical mortality rates in these patients are constantly decreasing.

and, at the same time, more extensive and formidable procedures are being successfully applied. Diseases of the heart and blood vessels represent the principal causes of death among patients who succumb during the postoperative period for reasons not directly related to the operative work. Our efforts must be directed toward making surgery even safer for these patients by concentrating on increasing our accuracy in the application of the details of surgical care so that mortality rates reach the irreducible minimum possible with present knowledge.

As physicians, entering a period in which the problems in geriatrics are on the increase, we owe a responsibility to our aged patients to approach the investigation of their illnesses with the same perspective that we do in the case of younger persons — that is, with the conviction that the outlook is not hopeless in many cases if surgery is needed. The high mortality rates among the elderly who must undergo surgery as an emergency can be avoided by earlier diagnosis and planned surgery at a safer time in a substantial number of cases. Early diagnosis and prompt acceptance of surgery in old patients with cancer seem to offer a particularly fruitful field for improvement.

In the preparation of this manuscript, I have received the helpful advice of many of my colleagues in the Department of Surgery. Particularly I wish to express my indebtedness to the members of the Carney Hospital Surgical Staff and to Dr. Herbert L. Lombard, director of the Division of Cancer and Other Chronic Diseases, Massachusetts Department of Public Health.

was diagnosed with plain films in 2 patients, and bronchography was therefore not done. There were no characteristic bronchographic findings to suggest foreign-body aspiration.

### Bacteriology

Bacteriologic examination of the sputum was done in only 5 patients. Alpha and gamma streptococci, *Staphylococcus aureus*, and *Haemophilus influenzae* were reported. The isolation of *H. influenzae* from the sputum of 1 patient led to a diagnosis of in-

### Operations

Lobectomies were performed in 7 cases, the right lower lobe being removed in 6 cases and the left lower lobe in 1. Hilar-dissection technic was used in all but 1 case. Dense pleural and diaphragmatic adhesions were encountered in 6 patients.

The postoperative course was uneventful in 6 cases. One patient with unusually extensive intrapleural adhesions and a long operation showed a low daily rise in temperature until the seventeenth postoperative day. There was incomplete pulmonary expansion and intrapleural fluid on the side of operation during this period. No wound complications were encountered. All patients were asymptomatic at the time of discharge.

### Follow-up Study

Follow-up information is available on all patients, the observation periods varying from two months to four years. The 7 patients who have had lobectomies are well. The one who had bronchoscopic removal of the timothy head without lobectomy has been well for four years.

### PATHOLOGY

The excised lobes showed similar pathologic changes, which varied only in degree. There were no specific changes that could be attributed exclusively to the action of timothy grass. Three of the lobes contained basilar abscesses, and in 2 of these the timothy was found by the pathologist. In the third, the timothy was removed at operation by rupture of the peripherally placed abscess while the pleural space was being dissected. The lobes in 4 cases showed classic bronchiectasis, as in Case 6 (Fig. 2), with irregularly dilated bronchi measuring up to 1 cm in diameter. The bronchial walls were thickened up to 0.6 cm. Timothy heads were found lying within ectatic bronchi in 2 cases. The timothy heads were always found stem downward, with their barbules pointing upward.

All lobes after removal were formalin fixed. Multiple tissue blocks were then obtained from characteristic areas, and sections were stained with hematoxylin and eosin, either Mallory's or Masson's connective-tissue method and Verhoeff's elastic-tissue stain.

The most striking histologic finding was extensive connective-tissue proliferation about the bronchi and vessels with extension along all the pulmonary septums. This was most marked in patients who had prolonged illness and was least obvious in those from whom the foreign body was removed bronchoscopically. Six cases showed a cellular intra-bronchial exudate. In 5 of these there was marked organization, with conversion of the exudate to active granulation tissue. The response of the bronchial mucosa varied from slight proliferation of columnar epithelial cells to production of thick

FIGURE 2 Hemisected Right Lower Lobe in Case 6, Showing Extensive Bronchiectasis

fluenzal pneumonia, and aerosol streptomycin was given without effect. No bacteriologic pattern characteristic of timothy aspiration was observed, although no special mediums were used.

### Duration of Foreign-Body Stay

The duration of stay of timothy in the bronchi varied from two to thirty-six months. In patients under the age of three the average stay was three months. In patients over six years of age the average stay was nineteen and a half months. In the 7 patients requiring surgery the period from the onset of symptoms to lobectomy varied from four months to three years.

squamous epithelium. Diffuse peribronchial infiltration with lymphocytes and large lymph-follicle formation in the submucosa were prominent in all cases. The elastic and smooth-muscle layers of the bronchi were disrupted and replaced by connective tissue and chronic inflammatory cells. Eosinophils, plasma cells and lymphocytes were the most common inflammatory cells in all lobes, but polymorphonuclear leukocytes were numerous immediately surrounding the abscesses. A marked intimal obliterative endarteritis was present in 4 cases, Fig. 3 shows the histologic findings in Case 7. This was most extensive near the diseased bronchus or abscess cavities. A large thrombosed and partially recanalized vein was found communicating with an abscess cavity in one lobe.

The alveoli of all excised lobes contained varying amounts of edema fluid, red cells, chronic inflammatory cells and macrophages. Some macrophages were fat laden, whereas others contained pigment. Multinucleated giant cells were occasionally present. The alveolar walls were variably thickened. In some areas alveoli were isolated by proliferating

months in the bronchi of the latter group. In addition, the timothy heads were more peripherally located in the lungs of the older patients.

Unstained smears were made of scrapings from the bronchial walls adjacent to the timothy head

FIGURE 4. Unstained Smear from the Bronchial Wall in Case 5, Showing Timothy Barboles (x63).

FIGURE 3. Cross Section of Timothy in the Bronchus in Case 7 with Masson's Trichrome Green Stain (x6). Note the marked obliterative endarteritis of the bronchial vessels and the thickening of the bronchial wall.

in 2 cases. Spicules of fibrous vegetable material were easily seen in both (Fig. 4).

#### CASE REPORTS

The following case histories are considered typical. In Case 3 the foreign body was removed bronchoscopically, but bronchiectasis had become established, so that lobectomy was ultimately necessary for cure. In Case 6 the foreign body remained undiagnosed for a long period and caused marked debility before lobectomy was performed.

**CASE 3.** C. F., a 2 2/12 year-old boy entered the hospital with a history of cough and intermittent fever after "swallowing" a piece of grass at the age of 17 months. A diagnosis of pneumonia was made, and chemotherapy given. The child was then taken out of the hospital against advice, but because of a continued septic course hospital care was sought again after an interval of 2 1/2 months. On this admission a foreign body was suspected, and at the first bronchoscopy a timothy tip was recovered from the right lower lobe bronchus. The patient subsequently improved clinically, but repeated bronchograms over the next 9-month period showed extensive and progressive bronchiectasis of this lobe. For this reason lobectomy was performed. Pathological examination revealed no additional foreign material. He has been asymptomatic for 1 year and no pulmonary complications have developed.

**CASE 6.** S. S., a 7 11/12 year-old girl gave the history of a choking spell at the age of 5 years after chewing grass in the early summer. One week after this episode she was hospitalized with a diagnosis of pneumonia. The infection did not respond to chemotherapy and empyema resulted. Three thoracotomies and later three rib resections were done. The patient was chronically ill and out of school for 1 year. Three years after aspiration she had a chronic cough, foul

connective tissue and were lined with darkly staining cuboidal epithelium.

In general, the diffuse acute inflammatory response was most marked in patients under three years of age. Localized abscess formation, diffuse chronic inflammation, fibrosis and obliterative endarteritis were all most marked in children over the age of six. However, the average sojourn of the foreign body in the bronchi of the former group was three months compared to nineteen and a half

sputum and x-ray evidence of bronchiectasis of the right lower lobe. The timothy was found in a subpleural abscess at operation, and lobectomy resulted in a cure.

### DISCUSSION

The Jacksons<sup>1</sup> have pointed out many reasons why the diagnosis of inspired foreign bodies is so often missed. Failure to elicit the history and failure to consider the possibility early in the course of the illness were the two principal reasons for misdiagnosis in the 8 patients described above. They illustrate the prolonged and disabling illness that may result when the correct diagnosis is not established. A foreign body was ultimately considered in all cases, but in only 1 was the timothy removed early enough to effect a cure without lobectomy.

The symptomatology is characteristic only of pulmonary infection unless a major bronchus is completely obstructed. In this event immediate massive atelectasis occurs with such severe symptoms that more aggressive efforts are usually made toward diagnosis. In this small series the correct diagnosis was established earlier in patients under the age of three. It is logical to assume that the smaller bronchi of very young children lodge the timothy at a higher point. Thus, the youngest patient in the series was bronchoscoped because of atelectasis following aspiration, and the timothy was removed. This was the only case in which lobectomy was not required.

In all 8 patients, as well as in those reported in the literature, the grass heads were oriented stem downward so that movement was possible in a peripheral direction only. In the older children with larger bronchi the grass progresses distally and is soon lost from bronchoscopic view. In this group localized abscess formation with empyema and pyopneumothorax is more common because of the subpleural position of the foreign body.

Severe hemoptysis in a child should immediately suggest the possibility of a foreign body. In 1 of the patients reported by Butler et al.<sup>5</sup> timothy fibers were found in blood coughed from the lungs. Timothy fibers were also found in smears made from the bronchi of the excised lobes in 2 cases of this series. These findings suggest the value of un-

stained smears of blood or bronchial secretions in the diagnosis of inspired vegetable foreign bodies.

The locality in which the patient lives and the season of the year are further clues to be considered. One would expect grasses or grains to be inspired during their flowering seasons. This season for timothy is during June and July in this locality.

The uniform operative procedures and the uneventful convalescence of these 7 patients illustrate the low risk of lobectomy in young patients. Even though the presence of a foreign body cannot be established, recurrent hemoptysis from an obviously damaged lobe or known bronchiectasis should be an indication for surgical treatment when tuberculosis has been excluded.

Two additional cases of Timothy grass aspiration have come to our attention since the completion of this study. In one of these bronchoscopic removal was possible.

### SUMMARY

Eight cases of timothy-grass foreign bodies in the bronchi are presented. Seven of these required lobectomy because of subsequent bronchiectasis or lung abscess.

The peculiarities of this foreign body are discussed.

No specific pathologic lesion was found in the cases presented.

Suggestions for early diagnosis are made.

We are indebted to the following for the use of their case histories: Drs. Ralph Adams, Robert E. Gross, Thomas H. Lanman, Richard H. Overholt, John W. Strieder, Richard H. Sweet, and Orvar Swenson, all of Boston, and to Dr. George E. Cummings, of Portland, Maine.

## COEXISTING PULMONARY COCCIDIOIDOMYCOSIS AND TUBERCULOSIS\*

LIEUTENANT (jg) ROBERT S STUDY (MC), USNR,<sup>†</sup> AND PHILIP MORGENSTERN, MD<sup>‡</sup>

ASHEVILLE AND BLACK MOUNTAIN, NORTH CAROLINA

## CASE REPORT

PRIOR to World War II, coccidioidomycosis was a relatively rare disease known chiefly to physicians in the San Joaquin Valley and a few other scattered areas in the southwestern portion of the United States. Winn,<sup>1</sup> in 1941, reported a series of 12 cases in which attention was called to the frequency of pulmonary cavitation as a manifestation of coccidioidomycosis.

During the war, when hundreds of thousands of troops were assigned for desert maneuvers in endemic areas such as Arizona, southern California and southwestern Texas, a large number acquired coccidioidal infection with pulmonary cavitation. As a result, many medical officers were brought into personal contact with the problem of differentiating the pulmonary lesions of coccidioidomycosis and those of tuberculosis. Several comprehensive articles have recently appeared in the literature dealing with all phases of the disease, including its roentgenologic differentiation from tuberculosis.<sup>2-4</sup>

Although there is no reason that tuberculosis and coccidioidomycosis cannot coexist, the literature contains only three such reports.<sup>4-6</sup> However, Dr C. E. Smith,<sup>7</sup> of Stanford University, indicated that he had seen a number of cases in which coccidioidal infection was superimposed on active pulmonary tuberculosis and 2 with tuberculosis superimposed on coccidioidal cavitation or active infection. Recently we observed a case in which caseous pneumonic tuberculosis with cavitation developed in a patient who already had a coccidioidal cavity in the opposite lung. Had we not known the previous medical history (at the time of the last admission), the finding of tubercle bacilli in the sputum together with the x-ray picture would have led to a diagnosis of bilateral cavitary tuberculosis, and the coccidioidomycosis would have been overlooked.

This case raises the question whether it would not be wise to do routine examinations for both coccidioides immitis and tubercle bacilli in all cases of pulmonary disease with cavitation. This is in line with the conclusions of Greer and Gemoets<sup>8</sup> that coexisting tuberculosis and fungous infection should be more frequently considered. In a series of about 300 cases of tuberculosis they found parasitic fungi in the tracheal washings in 4 per cent.

I F., a 24-year-old Negro was admitted to the hospital in December 1945. Pulmonary tuberculosis had been diagnosed on routine x-ray examination at a separation center that showed infiltration in both apices and in the right third anterior interspace.

During the war the patient had taken part in desert maneuvers in southern California from June to December, 1943, but had had no respiratory illnesses. The past medical history was noncontributory. The family history was negative for tuberculosis.

On admission the only complaint was intermittent, slight pain in the left side of the chest for the past few months. Physical examination revealed a well developed man who

FIGURE 1. Chest Film Taken on December 6, 1945, Showing Minimal Infiltration in Both Apices and an Area of Irregularly Annular Density in the Right Apex.

did not appear ill. There was no dyspnea or cyanosis and examination of the heart and lungs was negative. There were two healed scars over the left ankle and foot from an old gunshot wound.

A x-ray examination showed minimal infiltration in both apices (Fig. 1). Because of an area of irregularly annular density above the right clavicle, planigrams were taken on January 19, 1946, confirming the presence of a small thin-walled cavity (Fig. 2).

Significant laboratory findings at that time were as follows. A tuberculin skin test using purified protein derivative was negative in the first strength and weakly positive in the second strength. Coccidioidin skin test in a 1:1000 dilution was negative on two occasions. Sputum concentrates examination of the gastric contents, one sputum culture and one guinea pig inoculation were negative for tubercle bacilli. One 72 hour concentrate was negative for fungi. The sedimentation rate was 8 mm in 1 hour. Urinalysis showed a trace of albumin. Blood counts were within normal limits.

\*From the Department of Medicine and Surgery, Veterans Administration Hospital, Asheville, North Carolina.

†Published with the permission of the chief medical officer, Department of Medicine and Surgery, Veterans Administration Hospital, Asheville, North Carolina, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

‡Assigned by Navy to Veterans Administration Hospital, Asheville, North Carolina. Chief of Medicine, Veterans Administration Hospital, Asheville, North Carolina.

The patient left the hospital against advice in March, and the discharge diagnosis was chronic pulmonary tuberculosis, moderately advanced.

The patient returned to the hospital on June 13, with the chief complaint of bilateral chest pain and a slightly productive cough.

Physical examination and x-ray films of the chest showed no essential change since the previous admission. There was the same isolated, thin-walled cavity in the right apex and a small area of infiltration in the left apex.

A coccidioidin skin test was positive on July 2 in a 1:1000 dilution and positive on July 5 in a 1:100 dilution. Sputum studies for acid-fast bacilli, including seven direct smears, five concentrates and three gastric lavages, were negative. On July 15 the sputum was found to contain spherules of *Coccidioides immitis* on direct smear, and this was confirmed by culture on July 20. Serologic tests for active coccidioidomycosis were performed on August 31 by Dr. C. E. Smith, of Stanford University. The complement-fixation test was ++++ in 1:2 and 1:4 dilutions. The precipitin tests were all negative. Dr. Smith concluded that the findings indicated a coccidioidal infection.

Two attempts to close the right apical cavity with phrenicectomy were unsuccessful. Chloroquin was tried empirically, with no favorable result.

The sputum continued to be positive for *C. immitis*, but the symptoms of cough and chest pain cleared. Since at that time there was little evidence that the spherule form of

+++ in a dilution of 1:16. The precipitin tests were negative in all dilutions. Dr. Smith interpreted these results as not being high enough to indicate a coccidioidal dissemination. *C. immitis* was again found in the sputum on smear and culture.

The patient was recommended for streptomycin treatment of the exudative tuberculous lesion but left the hospital

FIGURE 2 Planigram Taken on January 19, 1946, Showing a Definite Thin-Walled Cavity in the Right Apex

*Coccidioides* was infectious,<sup>9</sup> the patient was discharged with maximal hospital benefit on February 19, 1947.

He was admitted for the third time on October 7, because of intermittent hemoptysis since March. He had also lost 10 pounds in the past 6 months. Examination of the chest revealed an impaired percussion note over the left apex posteriorly, with decreased breath sounds and post-tussive rales over the upper half of the left side of the chest posteriorly. X-ray examination on October 8 showed considerable enlargement of the thin-walled cavity in the right apex (Fig. 3). In addition, the upper third of the left lung was involved by a dense confluent type of infiltration, with several ill defined areas of radiolucence. The appearance of the lesion in the left lung was that of a fresh exudative tuberculosis. The temperature ranged between 98 and 99.6°F. Sputum examination showed acid-fast bacilli on both smear and culture. A serologic test for coccidioidal infection was repeated at this time by Dr. Smith. The complement-fixation test was ++++ in dilutions of 1:2, 1:4 and 1:8 and

FIGURE 3 Chest Film Taken on December 8, 1947. The thin-walled coccidioidal cavity in the right apex has enlarged. Caseous pneumonic tuberculosis, with cavitation, has developed in the left upper lobe.

against advice on November 1, before this therapy could be instituted.

### SUMMARY

A case is presented in which coccidioidal cavitation was observed for fifteen months in a patient who subsequently developed a caseous cavity tuberculosis in the opposite lung, with a positive sputum test for tubercle bacilli.

That tuberculosis and coccidioidomycosis may both cause pulmonary cavitation is now a well known fact. Also, since the diseases may coexist in the same patient, it is advisable to check routinely for both tubercle bacilli and *Coccidioides immitis* in all patients with pulmonary cavitation.

## MALARIA RELAPSE

## Report of a Case Thirty-Six Years after Original Infection

D KIRK SPITLER, MD\*

CLEVELAND, OHIO

THE problems of malaria control and treatment after the return of personnel from endemic areas have frequently been reported in the recent literature.<sup>1</sup> Not the least of these problems is the matter of relapse. Whereas this usually occurs within the first two or three months, there are reports of initial relapse one and a half to two and a half years after the original attack.<sup>2</sup> Relapses at longer periods have been observed, but these are in persons with recurring relapse, such as Ross's father, who suffered from repeated attacks for nine years after leaving an endemic area.<sup>3</sup>

The following case, in which the initial relapse occurred thirty-six years (or longer) after the original infection, is believed to be of interest.

## CASE REPORT

A 69-year-old Sicilian laborer was admitted to the University Hospitals, Cleveland on February 21, 1938 on the service of Dr J T Wearn. He complained of chills and fever occurring at "4-day intervals" for the preceding 6 weeks and a painful lump in the upper portion of the left side of the abdomen. "Four days before the onset of these chills he had slipped and fallen, striking the left side of the trunk on the street curbing."

The past history was significant in that the patient had been in the Sicilian Merchant Marine from the age of 7 to 33, calling at ports as far as the South Pacific. He had come to the United States in 1902 and had lived in the vicinity of Cleveland ever since. He stated that he had had one attack of malaria in Sicily, but he did not recall his exact age at the time. He denied any recent hypodermic injections.

Physical examination revealed a fairly well developed and poorly nourished, sallow man. He had bilateral lenticular opacities and gingivitis. Aside from occasional extrasystoles examination of the heart was negative, and the lungs were clear. The liver and the spleen could be felt during inspiration; the latter being slightly tender. The remainder of the physical examination was negative.

The temperature was 99.5°F, the pulse 88, and the respirations 20. The blood pressure was 162/88.

Urinalysis was negative. Examination of the blood disclosed a red-cell count of 4,590,000, with a hemoglobin of 90 per cent (Sahli) and a white-cell count of 3800 with 65 per cent neutrophils, 20 per cent small lymphocytes, 2 per cent large lymphocytes and 13 per cent monocytes. The parasites (*Plasmodium malariae*) of quartan malaria were seen within many red blood cells on the day of admission and on the following day.

On the 1st and 4th hospital days the patient had a chill after which the temperature rose to 105 and 104.8°F, respectively. He was given 1 gm of quinine sulfate after the second chill followed by 0.64 gm three times daily. Thereafter he had no further elevation of temperature and was discharged on the 9th hospital day with sufficient quinine to last for 1 week. He was followed in the outpatient department and was last seen at home in July, 1947. He had had no subsequent febrile illness.

## DISCUSSION

It is often difficult, if not impossible, to differentiate malarial relapse and reinfection, since the host

usually continues to reside in an endemic area. In the case reported above reinfection by natural means is highly improbable, and the possibility of previous parenteral medication was excluded.

As in the present case the relapse of malaria may occur at times and in places not likely in themselves to suggest the diagnosis. Diagnosis is further confused by the occasional atypical clinical course.<sup>4</sup> Hence malaria should be considered in any bizarre illness in a person who has either had malaria or resided in an endemic area. That the disease should recur after an interval of at least thirty-six years is admittedly unusual, but serves to emphasize the persistence of latent infection. Such latency, which constitutes a carrier state, illustrates the inadvisability of using as blood donors persons who have had malaria at any time in the past. The patient mentioned by Coggeshall,<sup>5</sup> who transmitted malaria by transfusion thirty-seven years after leaving his native country (Greece), where he had had malaria, further demonstrates this danger.

The cause of relapse in the case reported above is a matter for conjecture. It is now generally considered that during latent periods the plasmodia are undergoing cycles of development within the monocytes and reticuloendothelial cells, the so-called "exoerythrocytic cycle."<sup>6</sup> Trauma, extreme of temperature and fatigue frequently precede relapse.<sup>6</sup> The effect of these external forces is apparently to induce cyclic redevelopment of the parasites in the red cells, with the production of clinical malaria. Such a course may have occurred in this patient after the blow to the area of the spleen.

## SUMMARY

A case of relapse thirty-six years after the original malaria infection is presented.

## MEDICAL PROGRESS

### PILONIDAL CYST AND SINUS (Concluded)

JOSEPH LIBURT, M D \*

HUNTINGTON, NEW YORK

#### *Primary Closure*

In this method, after the diseased tissue has been excised, the wound is closed by various types of suturing, in many cases in conjunction with gluteal flap placements, all aimed at effecting successful closure

Ferguson and Mecroy<sup>30</sup> present 37 cases with 92 per cent cures following primary closure under a local anesthetic, an average healing time of seventeen and four-tenths days and two days lost from work

Cohn<sup>31</sup> advocates complete excision with primary closure, using a series of U sutures on either side of the wound edges to include the sacrococcygeal fascia, and finally tying the sutures over a small gauze roll. The patient is kept in the prone position for the entire length of healing

Camp and Polites<sup>32</sup> eliminate dead space by placing the deep and retention sutures beneath the sacrococcygeal ligaments, preventing infection by sifting sulfonamide powder through the closure

Oldham<sup>33</sup> reports 19 cases with 100 per cent success. He creates an elliptical area 12.5 cm or more long, and 7.5 cm or more wide, down to the ligaments of the sacrum and coccyx, and laterally down to the gluteus maximus muscles. He states that primary union can be obtained by aseptic technic, prevention of postoperative infection from the anus, complete hemostasis, obliteration of the cavity left after excision, avoidance of buried absorbable sutures and the use of an eversion suture

Glenn<sup>34</sup> in presenting 120 cases, stresses the postoperative care as follows: the dressings are arranged to seal off the anal region; tension is relieved by strips of adhesive tape extending well over the gluteal region, and a constipating diet, inhibiting the patient's bowels for six or seven days, is adhered to. The position in bed is on the side, with the face slightly downward and the legs straight. The gauze overlying the wound may be kept moist with alcohol, 10 to 15 cc being added every hour for the first six hours. Should the wound become infected, the sutures are removed, and packs soaked with an antiseptic solution such as Dakin's or dichloramine T are inserted

Shute, Smith, Levine and Burch<sup>35</sup> recommended a gluteus maximus flap. A wide double elliptical incision is carried down to the sacrococcygeal fascia,

from which the circumscribed tissue block is separated, a lateral incision down to the gluteal fascia in line of the original incision is then made on either side and deepened into the fibers of the gluteus maximus, and the fibromuscular flap thus created is sutured to its fellow of the opposite side, in the midline. Fifty-nine cases were presented, of which 48 healed primarily in eight days. The remaining 11 developed postoperative infection, healing in twenty-two days

Larsen<sup>36</sup> removes the lesion completely by elliptical block excision, and closes the wound with cotton sutures, employing a meticulous silk technic. Care is taken to place the deepest row of sutures at a level where the deep tissue can be approximated without tension, the sacral fascia is never included in the deep suture layer. Of 225 cases reported primary healing took place in 218, with secondary healing in 7

Pope and Hudson<sup>37</sup> presented 130 cases, with complete healing in all. However, they were unable to check for recurrences. In the 130 cases 92 patients were treated in conjunction with a sliding muscle graft obtained by gluteus maximus cleavage mobilization. The authors claim for this modification closure of all tissues, filling in of the dead space, rapid healing and a protective pad of tissue in the midline

Cattell<sup>38</sup> performs a block excision, with a transplanted gluteal pedicle flap, both ends of which remain attached for a better blood supply. A triangular flap is marked out, with the apex in the lateral gluteal region, on the side opposite the greatest defect made by the block excision.

Miscall and Holder<sup>39</sup> report 22 cases with primary union, utilizing musculofascial flaps, but admit that "insufficient time and observation, also the number of cases, do not permit any statement in regard to the rate of recurrence"

Hamilton, Custer and Kellner<sup>40</sup> in an analysis of 132 consecutive cases, find a 53 per cent failure in cases with a history of recurrent discharge or previous abscess formation, in addition to symptoms eight weeks prior to examination

Larkin<sup>41</sup> claims 90.9 per cent cures by his modification (a narrow strip of skin is removed in the midline (often no more than 0.5 cm in width). A block excision is effected through this space. No 30 stainless-steel sutures are placed 1.2 cm apart under the gluteal and sacrococcygeal fascia, after

\*Chief proctologist, Huntington Hospital

which 15,000 units of penicillin is administered every three hours until the eighth postoperative day.

Lahey<sup>3</sup> has conceived his own flap method. After block excision, a lateral incision is made parallel to one edge of the wound. Beneath this a bridge of skin and subcutaneous fat is separated from the gluteus maximus muscle so that the flap moves freely to the opposite side. The fat-lined bridge of skin is then displaced to the midline and sutured to the opposite edge of the wound to hold it in place. The defect resulting from transference of the flap is packed with gauze and allowed to close by granulation. When the resulting defect is small, Lahey brings the edges together.

Swinton,<sup>4</sup> using the Lahey method in 23 cases obtained 35 per cent recurrences, finding it difficult to prevent infection.

#### *Partial Closure*

The two chief exponents of the partial-closure method are MacFee<sup>5</sup> and McCutchen.<sup>6</sup> The former states that the principal drawback of primary closure is the constant presence of infection and difficulty in obliterating dead space. After removal of the diseased tissue, partial wound closure is effected by suturing of the skin edges to the sacrococcygeal fascia and underlying ligamentous structures, the skin edge on each side is brought as near to the midline as possible without tension, black silk sutures being used and a narrow undercovered area of fascia being left between. Furthermore, if the area is large enough to warrant it, he recommends a skin graft.

McCutchen,<sup>6</sup> while using the partial closure method, attempts to save skin in so doing two sides of a triangle are made on each side of the natal cleft, with the apex about 2.5 cm. from the midline and with either limb about 3.7 cm. in length. The apexes are joined across the midline by another incision (through the skin only), the lower flap is undermined to a point well below the coccyx, and the upper flap to a point well above the sacrum. The lateral flaps are formed by undermining of the incomplete triangles down to their bases, 5 gm. of sulfonamide powder is inserted, and stab wounds are made in all flaps, thus providing drainage for potential or actual infection. McCutcheon states that close apposition of the wounds is not desirable and that gross infection has appeared in a large percentage of his wounds.

#### *Open Method*

In the open method, all sinus and cyst tissue is excised, the wound being permitted to heal in by granulation. Smiley<sup>7</sup> favors the open method, with sclerosing solutions for the less complicated cases.

Carrington<sup>8</sup> performs subcutaneous excision beneath definitely placed flaps. The incisions are placed so that the bases are at right angles to the

long axis of the body (two to five such flaps), a midline scar being thus avoided.

Swinton<sup>4</sup> has performed operations in 85 cases via the open method in the past ten years, with a recurrence rate of 18.7 per cent.

Burns,<sup>9</sup> in a series of 240 cases, found 70 per cent cured by one operation, with a great majority cured by two operations.

Zieman<sup>10</sup> obtained cures in 100 per cent of cases with the open method, using wide excision, with an average stay in the hospital of two days.

Kleckner,<sup>11</sup> in a series of 160 cases, reports 100 per cent cures. In a questionnaire that he sent to fellows and associates of the American Proctologic Society (of which 75 per cent answered), 87 per cent were in favor of the open method, 75 per cent favored the closed method, and 55 per cent were undecided, using both open and closed methods. From the standpoint of cure, recurrence and safety, 70 per cent stated that there was no better method than the open one.

Tendler<sup>12</sup> stresses postoperative care: he repacks the cavity until the patient is discharged from the hospital, and insists on utmost cleanliness during the packing period. The patient is up on the fourth day and home in seven or eight days, and when the wound cannot hold packing, Sitz baths are instituted. Tendler is against too much activity, sitting or lying on the area after operation, poor hygiene and careless dressings. Tendler's cases heal in six weeks to two months.

#### *Discussion*

A glance at the highlights of the various technics impresses one with the fact that, regardless of the method employed, the average healing time, in sufficiently large series of cases, is anywhere from one to three months. When the healing time has been spectacularly shorter, one must assume that the lesion was small, confined and of limited infection, longer healing is assumed to be due either to faulty healing or technic or to more extensive disease.

Treatment with roentgen-ray therapy is inconclusive, and requires further investigation and a much larger presentation of cases before any definite conclusion can be reached.

The sclerosing method appears to have some merit in the self-limiting cases but hardly seems suitable for patients with a fairly long history of infections with lateral tract extensions. Although neurologists have been eminently successful in fixing the walls of gliomatous cysts with sclerosing solutions and various similarly acting solutions have been successful in the treatment of internal hemorrhoids and varicose veins, one fact seems to stand out in these categories: the lesion is sterile, whereas in pilonidal cysts and sinuses one is dealing with tissue that is basically infected. As in roentgen-ray therapy, the number of cases presented

by any particular therapist is quite modest (3 to 6), with only a relatively larger number studied by two authors (Heyd,<sup>18</sup> 25 cases, and Shafiroff and Doubilet,<sup>19</sup> 27 cases)

Marsupialization seems to offer no especial advantages. On Buie's<sup>24</sup> premise that the "deeper half of the lining of the cyst cavity, since it was originally intended to form skin, can be used to advantage in the surgical management of the problem," and Van Dyke's<sup>27</sup> statement that "since the cyst is ectodermal in origin, it will now perform its pre-designated duty as skin," one should expect 100 per cent cures. Unfortunately such a result is not obtained—and through no fault of the surgeon performing this technic. Two observations tend to modify the tenets of Buie and Van Dyke: the consensus on etiologic research (Gage<sup>4-6</sup> and Fox<sup>10</sup>) is that the lining of the cystic cavity can produce primitive skin appendages only, and the cyst cavity is usually infected. According to Van Dyke "infection in this area is the rule, and this may result in swelling of the tissues and cutting through of the sutures", Buie states that "if there has been no destruction by inflammation or erosive changes within the walls of the cyst or sinuses, then the cavity can be used to advantage in the surgical management of the problem." One must acknowledge that the cavity is usually infected, and this fact tends to vitiate the case for marsupialization.

So far as the use of the cautery knife is concerned, whether for the open or the closed method, I am not convinced of its superiority over the ordinary scalpel. One cannot get the same "feel" in cutting away infected, grumous or scarred tissue with the cautery as with the scalpel, the discoloration subsequent to cauterization beclouds the color of the healthy, yellow fat at the point where one stops the excision, and the coagulative effects may block off the openings of the lateral tracts, leaving them untouched.

The field, therefore, is thus narrowed down to the open versus the closed (including partial closure) method. Just as in the cases of roentgen-ray therapy, sclerosing solutions and marsupialization technic, the early and mildly infected cases may respond to the closed method. Since a patient ordinarily does not come to the surgeon for mere excision of a sacrococcygeal dimple or dimple sinus, one must conclude that the cases operated on are infected and that the surgery of pilonidal cyst and sinus is the surgery of infected tissue.

The ingenious devices of various sutures and gluteal flaps to eliminate dead space and to effect good primary closure bear eloquent testimony to the fact that something is basically wrong with the closed method. In other words, one carefully removes all apparently infected tissue and then carefully proceeds to close the wounds up—a process that the particular surgeon would never consider in surgery of infected tissue elsewhere in the body,

and with apparent disregard, as Nesselrod<sup>29</sup> so aptly puts it, of the "nearness of the operative field to the anal canal with its ducts, lymphatics and glands, and of the harboring of infection in the lymphatics adjacent to the sinuses and cyst itself." One obtains drainage and then fights to prevent egress of inflammatory products and finally broods about the recurrences.

The only hope for freedom from recurrence and of obtaining a good mechanical result, in case after case, lies in the open method. In performing the open operation, it is not necessary to remove large blocks of healthy skin and subcutaneous tissue, for it is then that delayed healing and a painful, tense scar occur, with the firm resolve that the next time, if it is done in the same manner, the operator will be sure to make up the defect by transposition of a gluteal flap or a specially devised suture placement. Similarly, a medical excision via the open method is likewise doomed to failure.

I believe that it is dangerous to employ a local anesthetic, for the needle is bound to drive inflammatory products into healthy zones. The interdiction against caudal anesthesia should certainly hold true for local infiltration. And it is just as well to interpolate that if the operation is not executed properly, the most meticulous aftercare, such as confining of the bowels, keeping the patient prone in bed for days on end with the legs straight, avoiding resting on the wound, blocking off the anus and supplementing with penicillin and sulfonamides, will all go for naught.

Except for the extremely rare cases of embryologic involvement of the neural canal through the sacrum, one should obtain 100 per cent cures by means of a properly performed open operation.

#### THE OPEN OPERATION

The method I use is based on a successful experience of twenty-two years. I do not claim it to be original with me. It is quite probable that others use a similar technic with their own personal modifications. With the procedure followed, there have been no known recurrences.

With the patient in the Depage position, and the buttocks spread via broad adhesive bands extending out to the edges of the table, one makes a longitudinal incision along the midline over the diseased area and then develops it until the sacrococcygeal fascia is reached. The length of the original incision is gauged by the external signs of the lesion. The incision can always be enlarged, consistent with the extent of the diseased tissue found on opening of the cavity. The one skin edge and wall is grasped with several Allis forceps, and the skin thus pulled back and everted. With the forceps as traction, all grumous, infected, scarred and discolored tissue is dissected out until healthy, yellow fat is seen on the wall. During the dissection, one looks for lateral tracts by observing small discolored areas in a field

of healthy fat. These areas should be probed and excised. The other skin edge and wall are similarly treated. If the fascia looks clean, it is left alone, if discolored in spots, those areas may be scraped. All the forceps are then removed, followed by a falling together of the skin edges of the wound. An Allis forcep is placed at either end of the incision, being held by an assistant so as to render the wound taut. The wound is saucerized symmetrically in an elliptical manner as follows: an elliptical piece of skin and subcutaneous tissue is removed from either skin edge along its entire length according to the size of the cavity. The widest portion of the ellipse is anywhere from 0.5 to 1.5 cm., with an average width of 1.2 cm.

There is then a wedge-shaped wound, narrowest at the bottom, widest externally, with all discernible diseased tissue removed. The wound is packed lightly with vaselized iodoform gauze, which is removed on the following day and never replaced. Hot Sitz baths twice daily are instituted on the first postoperative day. The patient may lie in any position in bed, and the bowels are not confined, any soiling being washed away with Sitz baths. The patient is up and around on the first postoperative day.

With a gloved finger, the bottom of the wound is broken up daily for the first few days and then less frequently as healing progresses, to prevent false closing or bridging over of granulation tissue. If the granulations are flabby or grow too fast on one side or the other, especially toward the external portion of the wound, they may be shaved down by the application of dipped 75 per cent silver nitrate applicators to the surface. Subsequent dressings consist of gauze, the inner surface of which is spread with vaseline to prevent sticking, and then a combine, all held in place with a T binder. The patient may go home in three or four days and may return to work in seven to ten days, depending on the wound size. Further postoperative care is continued in the office at the convenience of the patient in relation to his working hours.

If the operation is not a mutilating one — and there is no reason why it should be — the wound will close according to the extent of the lesion, in the usual one to three months, with a surprisingly small width of smooth, postoperative scar tissue.

The wound having been arranged rationally, there should be no difficulty in obtaining progressive closure. One should bear in mind that the gluteus maximus muscles act as effective purse-string sutures.

### SUMMARY

A review of the literature of the past fifteen years on pilonidal cyst and sinus is presented, delineating the highlights of the various techniques. A critical analysis of these methods is attempted, with the hope that the thoughts thus provoked may initiate a reorientation in the treatment of this pathologic entity. In addition, a technic is presented by which 383 cases have been treated over a period of twenty-two years with no known recurrences. The shortest healing time has been two weeks, and the longest fifteen weeks.

### CASE 34241

#### PRESENTATION OF CASE

*First admission* A forty-three-year-old type-setter entered the hospital because of epigastric pain.

Four years previous to admission he developed epigastric pain, hematemesis and melena. He was treated at another hospital for an ulcer though none was seen on x-ray examination. He obtained little relief of pain. In the two months before admission the pain became worse and was accompanied by vomiting.

When eight years old the patient had "rheumatism," and at about the age of fourteen years he developed a left upper, dorsal and a right lower dorsal scoliosis and a lumbar lordosis. Since then he had worn a brace intermittently. Six years before admission he had an attack of pleurisy, and several other attacks had occurred since then. Four years before admission he had an attack of pneumonia.

Physical examination revealed nothing remarkable except moderate emaciation and marked right dorsal scoliosis with rotation and prominence of the right chest posteriorly. There was some lumbar lordosis.

Examination of the blood disclosed 15 gm of hemoglobin and a white-cell count of 7200. The urine was normal. The stools were guaiac positive but later became negative. An x-ray film showed a deformed duodenal cap. The lung fields were clear.

The symptoms subsided on an ulcer regime. The patient was discharged improved after two weeks in the hospital.

*Second admission* (seventeen months later) The patient was followed in the Out-Patient Department and did fairly well for nine months, when he developed a cough and raised considerable sputum, some of which was bloody. There were no chills or fever. A pleural friction rub was audible over the right anterior chest. An x-ray film showed pleural thickening of the right lower lateral chest and an area of increased density anteriorly above the middle third of the chest, apparently in the right lung field. The sputum was negative for acid-fast organisms. The patient improved with bed

rest, the cough disappearing, but a pleural friction rub was audible for several weeks. He failed to gain weight and was weak but was eventually able to return to work.

Ten days before admission he developed a "head cold," which was accompanied by a cough. There was moderate sputum, at first rust-colored but later yellow and tenacious. Three days before admission he felt worse and became dyspneic and much weaker. A doctor gave him penicillin by mouth, but he felt no better and came to the hospital.

Physical examination revealed severe kyphoscoliosis (upper left and lower right dorsal, with rotation of the left chest dorsally). There was dullness over the lower lobe on the right, with diminished breath sounds. The breath sounds were bronchial in character over the right upper lobe. The left lung was normal. The heart was displaced to the left, and the pulmonic second sound was greater than the aortic second sound.

The temperature was 98.2°F, the pulse 95, and the respirations 20. The blood pressure was 105 systolic, 65 diastolic.

Laboratory examination showed a normal urine. Examination of the blood disclosed a hemoglobin of 16 gm and a white-cell count of 13,400, with 86 per cent neutrophils. The sputum was negative for acid-fast bacilli. Cytologic examination of the sputum was reported positive for tumor cells. X-ray films of the chest showed fluid in the right pleural space and increased density in the right upper chest, which appeared most likely to be consolidation in the right upper lobe.

The patient improved on penicillin. One hundred and seventy-five cubic centimeters of amber fluid was removed from the right chest. This had a specific gravity of 1.022 and contained 15,000 cells per cubic millimeter, of which 6750 were white cells. Some of the cells with Wright's stain resembled the cells in the sputum. A gallop rhythm developed, digitalis was given. The patient was discharged slightly improved on the fifteenth hospital day.

*Final admission* (fifteen days later) The patient grew weaker and was awakened at night by shortness of breath, which was relieved when he sat up. There was slight cough and almost no sputum. He had been taking 0.1 mg of digitoxin daily.

Physical examination showed cyanosis. The neck veins were distended and pulsating. There was moderate edema over the lumbar region. There was flatness over the right chest, with decreased breath sounds and tactile fremitus over the lower half. There were medium rales at the left base. The heart was enlarged, the border of cardiac dullness extending 10 cm to the left, with a strong point of maximum impulse. The rate was 120 with a regular rhythm.

The temperature was 98.2°F, the respirations 25, and the blood pressure 130/70.

The hemoglobin was 15.5 gm., and the white-cell count 15,400, with 87 per cent neutrophils.

Three hundred and ninety cubic centimeters of turbid, amber fluid was removed from the right chest in the Emergency Ward on the day before admission, and 700 cc. of similar fluid on the day of admission. The specific gravity of the fluid was 1.012. Following the tap the respirations became more labored, and the patient became comatose. He died on the day after admission.

### DIFFERENTIAL DIAGNOSIS

DR. MYLES P. BAKER: The first hospital admission eighteen months before death led to the following findings: duodenal deformity compatible with duodenal ulcer, probably active to judge from the presence of occult blood in the stools, persistent pain and vomiting, clear lung fields by x-ray examination, and pronounced dorsal kyphoscoliosis, with a story of repeated attacks of chest pain and one bout of pneumonia, such as these hunchback people are prone to develop. Deformity of the thoracic cage is most likely attributable in this case to poliomyelitis at the age of eight, with increasing scoliosis up to the time of adolescence, when fixation occurred. We hear no more about the duodenal ulcer, and I doubt if it had anything to do with the terminal illness. Nine months later he developed cough, — a new symptom, — with bloody sputum. X-ray study of the chest revealed a pleural process on the right side and a lesion in the right lung field as well. He made hard weather of it, with halting improvement, and obviously was losing ground.

An acute respiratory type of infection brought him to the hospital, with dyspnea, physical signs of fluid at the right base and consolidation or atelectasis with an open bronchus in the right upper lobe. X-ray studies confirmed the physical findings.

Three ominous findings appear on the second admission: the tumor cells in the sputum, similar cells in the pleural fluid, which contained red cells, and gallop rhythm. A man with a large pleural effusion and a displaced heart often has tachycardia and sometimes a suggestion of gallop rhythm. In this case it was considered serious enough to institute digitalization, so that I think the gallop rhythm was probably important and represented the "cry of the heart for help." It indicated probably myocardial damage and dilatation of the heart. The diagnosis in this case depends, I think, on two things — the appearance of the chest x-ray film, particularly regarding this shadow in the right lung field, and the "tumor cells" in the sputum and possibly in the pleural fluid. (Was this a Vincent Laboratory or a house officer's diagnosis?)

DR. TRACY B. MALLORY: Mrs. Graham, do you know about that?

MRS. RUTH GRAHAM: The report on the sputum was from the Vincent Laboratory.

DR. BAKER: I think it will be well to look at the x-ray films.

DR. STANLEY M. WYMAN: The first series of films shows the marked scoliosis described. The heart shadow cannot be adequately examined because of the chest deformity. The lung fields appear grossly clear on initial examination. Almost a year later another set of films shows no definite change except that one wonders about a little shadow of density extending outward from the right lung root. The films taken ten days later show an area of density extending in fan shape and involving the base of the right upper lobe. Some density is seen in the posteroanterior view. One cannot, however, see the bronchi adequately to determine whether or not there is occlusion of the major bronchi. This process continues in the subsequent films, with some collapse and areas of increased, rather spotty, mottled density in the right upper lobe. In some of the early films fluid is seen in the right pleural cavity. The last examination shows a large quantity of fluid occupying the right pleural space, and the right upper lobe is still further decreased in size. The density in the right upper lobe is hazy in character. This film shows unusual prominence of the pulmonary artery, in keeping with the finding of an increased pulmonary second sound. It is hard to tell about it because of the chest deformity.

DR. BAKER: Is the thoracic cage small?

DR. WYMAN: I think if measured volumetrically, it would be smaller than usual. Again, it is hard to say because of the deformity.

DR. BAKER: In this photograph that I have of the patient he looks much smaller from the diaphragm up than down.

I am told that the Vincent Laboratory has a very interesting absence of false positive cytologic diagnoses of cancer in examination of sputum specimens. In 5 or 6 cases the cytologic diagnosis has been an important primary indication of the diagnosis. Generally, of course, it has been confirmatory in proved cases of malignant tumor. It seems to me that with the x-ray picture of a hilar process producing atelectasis of the right upper lobe and the positive cytologic report from the laboratory we have good grounds for assuming that this man had bronchiogenic carcinoma to add to his serious handicap of kyphoscoliosis.

The question remains concerning the manner of death. We know that a year previously the chest film was clear. If we make the diagnosis of bronchiogenic carcinoma — a slowly growing tumor — as the sole cause of death, the patient died early. Was the manner of death in keeping with the diagnosis of pulmonocardiac failure described by Chapman\* in 1939? Some of the features of this patient's

\*Chapman, E. M., Dill, D. B., and Graybiel, A. Decrease in functional capacity of lungs and heart resulting from deformities of chest; pulmonocardiac failure. *Medicine* 18:167, '32, 1939.

death are so characteristic of this entity that I think it is worth elaborating upon briefly. It is pointed out by Chapman et al. that once these patients begin to fail, they survive only a short time, averaging about five months. This patient died within one or two months of the onset of symptoms of failure. At the last admission the picture was that of congestive failure—distended neck veins, edema over the back, rales at the left base, right pleural effusion and tachycardia. In these kyphoscoliotic persons habitual dyspnea is the rule—more so than the history indicates in the case under discussion. We do know that he was able to work only sporadically and felt weak prior to the second admission, he may have been dyspneic as well and taken that for granted over the years. Tachycardia is common, and edema rare and terminal, the accentuated pulmonic second sound is an outstanding physical finding. This man had it. There are no typical murmurs in this particular symptom picture. Cardiac enlargement, which I believe he had, is difficult to be sure about because of the chest deformity, as Dr. Wyman has said. Electrocardiograms are notably normal in the majority of cases and bronchial infections are rather common in these handicapped people and very likely, as in this man, to be one of the features that tip the very precarious balance in favor of failure. Digitalization and the use of diuretics are characteristically fruitless with such a handicapped pulmonary function, already diminished by bronchial infection. This is just the sort of added load that produces pulmonocardiac failure in such a patient. I think the findings in this case support such a hypothesis. The patient was singularly ill suited for the development of bronchiogenic carcinoma. The first manifestations of pleural irritation, as well as the development of pleural fluid and bronchial infection, in an atelectatic lung, were more than enough to tip the balance in favor of pulmonocardiac failure. I think that autopsy will show small lungs with evidence of acute bronchitis and parenchymal infection, congestive failure, probably a dilated right ventricle and bronchiogenic carcinoma.

DR. MALLORY: Dr. Bland, what did you think about this case?

DR. EDWARD F. BLAND: I happened to be in charge when the patient was on the ward, and in retrospect there were several remarkable things that it might be interesting to call attention to. Apparently we were so engrossed with what was going on in the lungs that an electrocardiogram was not taken. I do not believe that it would have clarified the situation because it probably would have been normal, as Dr. Baker has suggested, except for tachycardia. When the patient came in he was quite ill. The first impression both on the ward and in the Pulmonary Clinic where he was seen was that of an acute pulmonary infection, which improved temporarily with penicillin. However, he

continued quite ill. Since we could not find acid-fast bacilli in the sputum we asked the Vincent Laboratory to examine the sputum and the chest fluid. The report on the sputum came back with the unequivocal diagnosis of tumor cells. Other sources of opinion were not so certain that they were tumor cells. We asked the Pulmonary Clinic to review the situation in the light of the sputum findings. At that stage, in spite of the positive cytologic evidence of cancer, the Pulmonary Clinic was not convinced about the presence of tumor. One might wonder why bronchoscopy was not performed. That seemed inadvisable because of his poor condition and the marked deformity, as well as an element of heart failure. Why did we not give some form of treatment? Estrogens were contraindicated because of the congestive failure, and we did not want to waterlog the patient any further with sodium retention. X-ray therapy was considered and discarded by the Tumor Clinic. Therefore, since he was reasonably comfortable we let him go home and asked him to return if he became more uncomfortable, which he promptly did.

DR. F. DENNETTE ADAMS: Would this electrocardiogram not show right-axis deviation because of the deformity of the chest?

DR. BLAND: About a fifth of the cases show right-axis deviation.

DR. MALLORY: Mrs. Graham, have you anything to say?

MRS. GRAHAM: No, except that smears of the sputum were definitely consistent with epidermoid carcinoma.

#### CLINICAL DIAGNOSIS

Kyphoscoliotic heart disease  
Bronchiogenic carcinoma?

#### DR. BAKER'S DIAGNOSES

Pulmonocardiac failure ("scoliotic heart disease"),  
with right ventricular dilatation  
Kyphoscoliosis, dorsal, severe  
Bronchiogenic carcinoma

#### ANATOMICAL DIAGNOSES

*Bronchiogenic squamous-cell carcinoma, right upper lobe*  
*Kyphoscoliosis*  
*Cor pulmonale*  
Pulmonary abscess  
Bronchiectasis, right upper lobe  
Pulmonary atelectasis

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: Post-mortem examination showed bronchiogenic carcinoma of the right upper lobe. This man was not a person who could have been subjected to bronchoscopy, although it would have been very easy to obtain a biopsy since the tumor had extended into the right primary bronchus.

There was the severe thoracic deformity that has been described, and there was very little useful pulmonary tissue at the time of death. The right upper lobe showed beyond the obstructed bronchus an abscess cavity and also rather diffuse bronchiectasis. There was marked collapse of both lower lobes, so that the patient had very little except the left upper lobe with which to breathe. There was pleural effusion—not much—about 200 cc on each side, but with his small chest that was significant. The heart was slightly hypertrophied, particularly the right ventricle, which was dilated and, nevertheless, had a thickness of 6 mm.

It certainly seems as if an electrocardiogram should have shown right-axis deviation if it had been obtained. There were no metastases except to the regional lymph nodes at the hilus, so that I think Dr Baker's prediction is correct that cancer was not the cause of death but it was the acute pulmonocardiac failure that one sees so regularly with this type of chest deformity.

There was one puzzling feature: the liver showed granulomas, which I could not identify. They did not look much like tubercles. The microscopic sections were negative for acid-fast bacilli. I think that he did have a terminal infection, which I could not identify. Post-mortem cultures showed a mixture of colon bacilli and nonhemolytic streptococci, probably a contaminant rather than anything significant.

DR BENJAMIN CASTLEMAN: What type of carcinoma?

DR MALLORY: It was a well differentiated squamous-cell carcinoma.

DR BLAND: Did he have a gastric ulcer?

DR MALLORY: None that we could find. He had a dilated esophagus suggesting cardiospasm, which sometimes produces symptoms similar to those of a gastric ulcer.

A PHYSICIAN: You say that there were no metastases except to the hilar lymph nodes—no evidence of pleural involvement? I ask because of the fluid findings.

DR MALLORY: No, we did not find any pleural involvement.

## CASE 34242

### PRESENTATION OF CASE

A seventy-nine-year-old widow was admitted to the hospital because of shortness of breath and chest pain.

The patient complained of pain beneath the left breast nine days before admission, and three days later the pain became severe, radiated down the left arm, and was accompanied by shortness of breath. A physician found the blood pressure to be 138 systolic, 60 diastolic, the pulse was 100 and regular, and there were basal rales and slight edema

of the ankles. An electrocardiogram taken on the following day showed normal sinus rhythm, small Q waves in Leads 1 and 2, a small R wave, a secondary R wave and a deep S wave in Lead 3. The T waves in Leads 1 and 2 were upright, and the T wave was upright but diphasic in Lead 3. The patient also complained of pain in the right thigh. The symptoms subsided with bed rest, digitalis and diuretics. Thirty-six hours previous to admission the dyspnea and pain in the left chest recurred. These gradually became worse and were accompanied by cyanosis and several episodes of vomiting.

The patient had been hospitalized nine, eight and seven years before admission because of what the family thought were heart attacks. Four months before admission she was seen by the family physician, who found moderately advanced congestive failure and a blood pressure of 180 systolic, 100 diastolic. She complained of backache, but an x-ray film showed only osteoporosis. Six weeks before admission the patient underwent an appendectomy at another hospital. The diagnosis was acute suppurative appendicitis. The postoperative course was uneventful except for a staph abscess.

Physical examination revealed a disoriented, cyanotic woman. The neck veins were distended and pulsating while she was in a semierect position. The heart was slightly enlarged. There was a slight apical systolic murmur. The aortic second sound was equal to the pulmonary second sound. The breath sounds at the left base were less distinct than those on the right. There was diffuse tenderness in the right lower abdomen, with a healing staph abscess in the appendectomy scar.

The temperature was 101.2°F, the pulse 80, and the respirations 32. The blood pressure was 135 systolic, 55 diastolic.

Examination of the blood revealed a hemoglobin of 13 gm and a white-cell count of 16,400, with 84 per cent neutrophils. The nonprotein nitrogen was 49 mg and the serum protein 7.02 gm per 100 cc. The urine gave a ++ test for albumin, and the sediment contained 1 or 2 pus cells and numerous hyaline casts per high power field. X-ray films of the chest with the patient recumbent showed unusual prominence of the right pulmonary artery, and the linear markings were less numerous on the right than on the left. There was a suggestion of an abrupt termination of what might have been the pulmonary artery on the right. There were irregular areas of density in the upper lungs with some calcification. There was an area of irregular, strand-like density at the left base, with obscuration of the left costophrenic sulcus. There were hypertrophic changes in the thoracic spine, with some increase in the anteroposterior diameter of the chest. A film of the abdomen was not satisfactory. An electrocardiogram showed normal rhythm, a PR interval of 0.2 second, a normal

axis and small Q waves in Leads 1,  $V_4$  and  $V_5$ . The ST segments were depressed in Leads 1, 2, 3, VF,  $V_2$ ,  $V_4$  and  $V_5$ , the T waves were inverted in Leads 2, 3, VF and  $V_2$  and seminverted in Leads 1,  $V_4$  and  $V_5$ .

On oxygen the patient became much less dyspneic. She was given digitalis, ammonium chloride and penicillin (300,000 units daily). The temperature returned to normal. An x-ray film of the chest taken on the seventh hospital day showed less prominence of the right pulmonary artery, although again there was a suggestion of diminution in the vascular markings in the lower portion of the right lung field. There was an area of density at the left base. There was little change in her condition until the eighth hospital day, when she suddenly collapsed. The blood pressure was 100 systolic, 50 diastolic, and the pulse 90 and totally irregular. She complained of substernal pain. An electrocardiogram showed a different rate of auricles and ventricles, which was probably due to digitalis toxicity. On the following day she was worse, but the neck veins were not distended and she was not cyanotic. The abdomen became distended and diffusely tender. A stool specimen was guaiac positive. She became unresponsive and died on the tenth hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR EDWARD F. BLAND: The perspective of the abstract as read is slightly confusing, and hence it seems worth while to recapitulate the more important events. We are presented with a seventy-nine-year-old woman, who had an indefinite history of what was thought to be heart attacks seven, eight and nine years previously, perhaps they were heart attacks, but she got along very well otherwise until near the end of her life. The terminal illness began about four months before entry to the hospital, when she was found to have moderate hypertension and congestive failure. The latter seemed to respond to therapy until six weeks before entry. At that time she developed an acute condition of the abdomen, which required operation and a suppurative appendix was found and removed. Nine days before entry she had sudden pain in the left chest, with dyspnea and also pain in the right thigh—nothing more is said about the legs, however, from then on. An electrocardiogram was uninformative, being consistent with an aging heart and perhaps a digitalis effect. This sudden chest pain, it seems to me, must have been due to a pulmonary infarct. She might have had a myocardial infarct, but the symptoms are more suggestive of trouble in the lungs than in the heart. She again did well until thirty-six hours before entry, when a similar attack came on abruptly, which again sounds more pulmonary than cardiac. From then on she progressed slowly downhill. On entry she was a very aged and a very ill woman, with evidence of congestion and mild uremia. She was

febrile and had a suspicious tenderness in the right lower quadrant. The legs are not mentioned, I would be interested to know if they were all right.

DR HELEN S. PITTMAN: They were.

DR BLAND: The X-ray Department made some interesting comments. The films were probably taken with a portable machine, but they must have been unusually good to permit the observations recorded above. We had better look at them.

DR STANLEY M. WYMAN: We have two series of films, the second examination being done two days after the first. These interpretations were made by Dr. Joseph Hanelin of our department, and I think his observations were very astute. The right main pulmonary artery is seen at this point, the lower margin is unusually sharply defined and clear-cut. It seems to have a lobulated termination quite in contrast to the usual lower termination of the pulmonary artery. The fine mottling and calcification in both upper-lung fields are probably of long standing. The areas of linear density and the fibrosis at the left base are probably old. There seems to be in the entire right lower-lung field a paucity of vascular markings in comparison to the left. This is a valid observation although the patient is slightly rotated. The chest is considerably increased in the anteroposterior diameter, suggesting some degree of emphysema.

DR BLAND: The heart is not very large, is it?

DR WYMAN: It is impossible to measure it accurately. The patient was lying down. The measurements in this position would make the heart about 13 cm. as compared with 22 cm. for the chest.

DR BLAND: The left lung is smaller than the right?

DR WYMAN: That is due to rotation of the chest cage.

DR BLAND: The lung roots are dense, with abrupt cessation of the right main pulmonary artery shadow?

DR WYMAN: I believe that is so. The left main pulmonary artery does not show such a configuration. The second film shows considerable change in the right main pulmonary artery, again suggesting termination there. This film shows the large fibrotic process at the apex.

DR BLAND: There is nothing new in the second film—just a little fluid at the left base perhaps.

DR WYMAN: I do not feel safe in thinking that is the costophrenic angle posteriorly. It seems to be sharp on both sides. The films of the abdomen, which were taken with a portable machine, show no gross abnormality.

DR BLAND: It would have been helpful if she had been well enough for fluoroscopy because the right pulmonary artery is enlarged and ends abruptly—it must be obstructed at that point.

DR WYMAN: It looks unusual.

DR BLAND: It would be helpful to know if it pulsated.

Dr WYMAN That is pretty essential

Dr BLAND During the hospital stay the patient was treated for heart failure and infection. Nevertheless, she slowly worsened and went into a terminal collapse of some sort with arrhythmia of the heart, and died two days later. These terminal events were interesting. Was this abdominal film taken at the end?

Dr WYMAN It was taken about two days before death.

Dr BLANN The clinical picture is complicated by the septic appendix, which was removed, and the suspicious persistence of tenderness in the abdomen, the terminal distention, diffuse tenderness and a positive guaiac test on the stools. Nothing is said about a tender liver, and the veins were not engorged when the abdomen was becoming distended. Therefore, hepatic congestion was not responsible. The other possibility is mesenteric thrombosis or embolism, with intestinal infarction. Also, as a result of that or possibly as a result of a residual infection from the appendix, peritonitis must have developed terminally.

In conclusion, therefore, this patient had hypertension and coronary-artery disease. Congestive failure seems to have been definite, and I believe she also certainly had pulmonary infarcts. Other complications are probable but seem somewhat less well defined. I am intrigued by the x-ray appearance of the right hilus. She must have had a thrombus obstructing the right pulmonary artery. Furthermore, she probably had old myocardial infarcts, from the history she might even have had a recent one, but we cannot prove it from the electrocardiograms. I think that something acute was going on in the abdomen at the end, being due, I suspect, to a mesenteric thrombus or embolus, with intestinal infarction.

We might mention in passing that when elderly people die in this fashion there are two things that sometimes turn up as unexpected findings. One is bacterial endocarditis. I do not believe that this patient had that. The other point that one should keep in mind in the face of progressive thrombophlebitis and pulmonary infarcts is a malignant tumor in the abdomen. We have no right to make such a diagnosis on the data given.

Dr F DENNETTE ADAMS Dr Bland, in the presence of pulmonary infarction—which you believe was present in this case (and I do too)—what is your evidence for congestive failure? Do you have to add congestive failure to account for the picture if you assume pulmonary infarction?

Dr BLANN The most suggestive finding is the swollen neck veins, which seemed to be definite when she came in. Is that correct, Dr Pittman?

Dr PITTMAN Yes.

Dr BLAND Her physician made a diagnosis of heart failure four months before the acute episode

here. The heart, however, on x-ray examination, did not look like it.

Dr ADAMS Can distended neck veins occur with pulmonary infarction?

Dr BLANN They may, with massive pulmonary embolism.

Dr PITTMAN The original note says that the patient was sitting up in bed with gasping respirations and that the neck veins were distended and pulsated in both clavicles in a semierect position.

Dr BLANN In view of this I think we must assume an element of heart failure. We do not know about the liver. People with swollen neck veins from heart failure have large livers too.

Dr ADAMS May I ask one other question?

Dr BLANN Yes, but do you think she did or did not have congestive failure?

Dr ADAMS I do not feel sure about it. I would stick to pulmonary infarction. She may well have had peritonitis, I am always suspicious of the diagnosis of stitch abscess.

Dr WYMAN RICHARDSON There is no mention that anyone looked at the blood smear to see if she had neoplasm or infection.

Dr ADAMS I think she might have had both—probably acute peritonitis, which in older people is so often overlooked.

Dr PITTMAN This was a difficult problem. The patient was an old and very sick woman in whom the history and the findings were very confusing. We deliberated long on the morning following admission regarding whether the more reasonable probability was myocardial infarction or pulmonary infarction, at that time she had some cyanosis, a fall in blood pressure, transient leukocytosis, then a white-cell count of 6000, no change in breath sounds and no elevation of the respiratory rate, so that I leaned to the side of a myocardial rather than a pulmonary process as the basic disease. Five days later she had been got up in a chair for a few minutes, but she suddenly felt weak, the legs collapsed, at that time the heart rhythm had become irregular, and she was gasping and complaining of a very severe pain substernally. We thought that it might be another myocardial infarction or might very well be a pulmonary infarct. In the next thirty-six hours the signs and complaint shifted completely from above the diaphragm to the abdomen. She had a silent abdomen. It was very tender and she began to produce guaiac-positive material whereas previously it had been guaiac negative. We believed that mesenteric thrombosis was the most reasonable explanation. She died very quickly after this abdominal episode, and the house officers at the time of death put down the diagnosis as question of coronary thrombosis, question of pulmonary embolus and question of mesenteric thrombosis.

Dr BLANN Would it be unusual, Dr Mallory, for a patient of this age, after a four months' ill-

ness in and out of bed, to turn up in your department without a pulmonary embolus?

DR TRACY B MALLORY I think most of them would have one

#### CLINICAL DIAGNOSES

Coronary thrombosis?  
Pulmonary embolus?  
Mesenteric thrombosis  
Arteriosclerotic heart disease.  
Congestive failure

#### DR BLAND'S DIAGNOSES

Hypertension and coronary-artery disease  
Pulmonary infarcts  
Thrombosis, right pulmonary artery  
Mesenteric thrombosis (or embolism)  
Peritonitis?

#### ANATOMICAL DIAGNOSES

*Pulmonary emboli, multiple*  
*Thrombi of right ventricular endocardium*  
*Thrombosis of left popliteal vein*  
Myocardial infarction, very recent  
Segmental gangrene of bowel  
Arteriosclerosis, generalized, severe  
Cholelithiasis

#### PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed multiple pulmonary emboli of varying ages. There was complete blockage of the right main pulmonary artery, as the X-ray Department had predicted. A great many of these emboli had evidently been present from days to weeks since considerable degrees of organization were present. The heart weighed 360 gm — slight hypertrophy for a woman. The right ventricle contained thrombi behind and around the columnae carneae. These were adherent, and microscopical examination showed that they, too, were partially organized. There was also an area of acute hemorrhagic discoloration in the interventricular septum. This, however, was evidently fresh and

acute in contrast to the intracardiac thrombi, which must have been present for a much longer period. A second possible source of the emboli was the popliteal vein on the right, where there was some thrombotic material. We could not say with certainty whether the emboli found in the lungs came from the leg veins or from the right side of the heart. The coronary arteries were not sclerotic but appeared wide and capacious, remarkably good in view of her age.

The bowel showed a segment of acute hemorrhagic enteritis with hemorrhagic necrosis of all layers of the wall. This was 22 cm long, but careful dissection of the arteries and veins in the corresponding mesentery did not disclose thrombi in either system. Whether she had had an intussusception or volvulus that had reduced itself or whether we failed to find the embolus, I cannot say with certainty.

There were various other coincidental findings that a woman of seventy-nine might have, including a gall bladder full of stones and a completely stenosed cervical canal, which in a younger woman would have led to pyometrium and other complications.

DR BLAND Why do you think the thrombi formed in the right ventricle?

DR MALLORY I cannot say. There was no evidence of infarct beneath the areas of thrombosis.

DR BLAND She was not fibrillating. The heart was not large.

DR BENJAMIN CASTLEMAN Could the thrombi have come from the leg veins — emboli that had become arrested in the ventricle and become attached?

DR MALLORY I suppose it is conceivable. I have never seen it happen.

DR BLAND Do you recall what the left base looked like? Was that infarcted?

DR MALLORY Infarcted — there was no fluid on either side.

DR BLAND The X-ray Department is to be congratulated on pointing out the finding of an obstructed pulmonary artery, and from films taken with a portable machine.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 5 Fenway Boston 15 Massachusetts. Telephone KE 6-7094.

## ONE HUNDRED AND SIXTY-SEVENTH ANNIVERSARY

The recent annual meeting of the Massachusetts Medical Society, making its one hundred and sixty seventh anniversary, was one of the best attended and most successful meetings in the history of the Society. The number of registrants totaled 2436. At the Council meeting, held on May 24, a number of currently important subjects were discussed in addition to the routine acceptance of committee reports.

The matter of better emergency medical service, which has caused mild agitation in recent months, was referred to the district societies for consideration and solution. A supplementary report of the Committee on Finance called attention to the new classification into which the Society has been placed by the Treasury Department and the Massachusetts Division of Taxation. This classification so modifies the status of the Society as a charitable, benevolent and educational organization as to render it liable for old-age assistance and unemployment levies.

The subject of the physician's unsatisfactory situation regarding procurement and assignment during the recent war was brought up, and the present bill before Congress relative to the drafting of physicians in case of a national emergency was condemned.

The following officers were elected for the year 1948-1949: president, Daniel B. Reardon, president-elect, Arthur W. Allen, vice-president, Donald Munro, secretary, H. Quimby Gallupe, treasurer, Eliot Hubbard, Jr., assistant treasurer, Norman A. Welch, orator, Charles Sidney Burwell.

Dr. Reardon, in acknowledging his introduction as incoming president, emphasized the duty of the Society to explore the roll of physicians in the Commonwealth who are not now fellows, that those who are eligible for fellowship or who can become eligible, may be encouraged to achieve that status. Dr. Reardon's address is printed on the following pages of the *Journal*.

At the annual meeting of the Society on May 25 certain amendments to the by-laws were accepted, the chief of which changed the secretaryship of the Society to a full-time position. The President then reported on "the state of the Society," members of the Society fifty years in practice were introduced, and honorary fellowship was conferred upon Sir Reginald Watson-Jones, of London, orthopedic surgeon to H. M. George VI and surgeon-in-chief of the Royal Air Force. The annual oration, which has already been published in the *Journal* of May 27, was delivered by Dr. Allen S. Johnson, of Springfield.

The Shattuck Lecture, appearing elsewhere in this issue of the *Journal*, was delivered on the evening of May 25 by Dr. C. Stuart Welch, professor of surgery at Tufts College Medical School.

The newly formed woman's auxiliary of the Society held its organizational meeting on May 26, at which time the following officers were elected: president, Mrs. Leighton F. Johnson, of Wellesley Hills, vice-president, Mrs. Charles C. Ayers, of Worcester, secretary, Mrs. John F. Conlin, of Boston, treasurer, Mrs. Leo G. Rondeau, of Boston.

At the annual dinner on May 26, Mary Ellen Chase, Ph.D., Professor of English Language and Literature at Smith College, addressed a capacity audience on the subject of "The Country Doctor on the Maine Coast."

The scientific papers, as usual, were of high caliber, and the sessions were well attended. The scientific and technical exhibits aroused interest, and great credit is due to the Committee on Arrangements and the indefatigable executive secretary.

# MASSACHUSETTS MEDICAL SOCIETY

## PRESIDENTIAL ADDRESS

I find it difficult to express the sentiments that are mine as I assume the chair of president of this ancient brotherhood. Surely among thousands of the professional societies of our nation it is unique, for it combines the traditions of long years with policies dedicated to the forward march of medicine in this well loved Commonwealth of ours. No one who has spent nearly fifty years as student and practitioner in the field that binds all here together can take this chair without strong pride that his brothers have placed their faith in him and that he may serve honorably and well in the footsteps of all those men who have preceded him, from Edward Augustus Holyoke in the beginning to our own Edward Parsons Bagg today. To Dr. Bagg particularly go my thanks for his kindness and help to me during the period of education that has been mine as president-elect. To the chairmen of all our working committees who have extended invitations to me to attend their many meetings during the past twelve months, I also express my gratitude. And to yourselves, representing as you do our large and distinguished fellowship, I convey my heartfelt appreciation for the confidence reposed in me that my election to the presidency indicates. I promise you I shall not fail you. The honor done me is freighted with responsibility. That I recognize and accept.

The careful discharge of the duties of the office of president, however, depends in large measure on the co-operation extended by those of our members who serve upon our numerous committees. Committee work such as ours must necessarily be calls for much corporate dedication of time and effort. The only thanks in return for this sacrifice is the knowledge of our committee members that by their labors they have advanced the profession in those avenues in which their work lies, but *that* is reward sufficient to most. I have been greatly impressed, during this year of apprenticeship just past, to see the remarkable fidelity of the men on a number of our more important committees, and I can but commend their example to those who enter upon such work for the first time this year. To the incoming President-Elect I pledge my assistance that he may arrive at his post as President next year as liberally educated as I believe I am today in the many and various endeavors that we are carrying forward.

I propose also to explore new territories in which the Society may prove its worth to the profession. We have some 2000 physicians in the Commonwealth who, for one reason or another, are not numbered in our membership. The continuance of our strength depends in large measure on our numbers. Every properly qualified physician should be with us. For

those not with us an analysis should be undertaken to determine whether the fault be theirs or ours. I have the strong opinion that the coming years are going to find us under various forms of attack as a profession. We must meet such onslaughts with a major force, that when we speak we shall speak with the authority that the weight of numbers conveys. We should do all in our power to assist those men in practice outside our ranks who are substandard by education or experience. For them as well as for our members, the committees on the Postgraduate Assembly and Postgraduate Medical Education under Drs. Parkins and Ohler have done much. I state the hope that we may do even more.

The issuance of membership cards duly certified to members in good standing is a matter that might receive some consideration by the Council, in the light of practice elsewhere among professional societies, and also for the purpose of identification, which seems to become important in some quarters from time to time.

Another question that has been brought to my attention by some of our members has to do with the fundamental well-being of many of the members. I judge that I am right in saying that the great majority of Massachusetts physicians are not on salary. They, therefore, in common with all the self-employed do not in any way share in the retirement and old-age benefits extended to many nonprofessional executives.

You are aware of cases in which old age in a doctor has brought financial distress. Too often, improper husbanding of capital and income during the earning years has led to a standard of living that the physician finds it impossible to maintain in his advanced years. Present high prices serve but to emphasize the dilemma that confronts many of our members. I have had occasion during the past year to look into the question of some system of retirement benefits for the members of the Society, and I understand that several of the local bar associations are in the process of similar investigation. Two facts are clear at this moment. One is that present law on our statute books prevents us from moving forward on any such program were it agreeable to the Society. If, after due consideration, it appears wise to go further I should suggest that in company with other like-minded groups we might move to seek amendatory legislation opening the way for enjoyment by our members on a contributory basis of the same program that has proved itself a boon to many other groups. A second fact of importance here is that the Congress of the United States has under advisement an extension of the Social Security program to the self-employed and to the professions on a voluntary scale. National action might well be the

answer to the problem I have just set out. My belief, is, however, that the appointment of a committee by your authority, to go over this entire matter might be a wise move.

These, then, are a few of the thoughts on my mind at our meeting today. As I said at the beginning, my entry into the presidency of the Society caps for me a lifetime in the practice of the medical profession, and means more to me than anything I might ever have achieved. We are all inheritors from some very great men. Where else might one search in the world for the medical progress that has marked the history of this Commonwealth, small in area and large in influence, in the last century and a half? It is the task of all of us to carry the torch as high as our predecessors placed it. I recall that Arthur Balfour, writing of the work of the First Harvard Unit (to which I had the good fortune to be attached) during World War I, said, "They have added luster even to the fame of Harvard." May it be said of us working together during the next twelve months "And they have added luster even to the fame of the Massachusetts Medical Society." With that high goal and in that spirit, may we enter upon our respective duties in the sure knowledge that we will not fail!

DANIEL B. REARDON

## DEATHS

**COLE**—William G. Cole, M.D., of Pittsfield, died on April 16. He was in his forty-seventh year.

Dr. Cole received his degree from Columbia University College of Physicians and Surgeons in 1928. He was a member of the American College of Radiology and a fellow of the American Medical Association. He was roentgenologist in chief at House of Mercy Hospital.

His widow and a daughter survive.

**CONNOR**—George J. Connor, M.D., of Haverhill died on April 19. He was in his sixty-second year.

Dr. Connor received his degree from Maryland Medical College in 1909. He was a counselor of the Essex North District Medical Society and chairman of the Committee on Public Relations, chairman of the Haverhill Board of Health and a fellow of the American Medical Association.

His widow survives.

**GILBERT**—Maurice A. Gilbert, M.D., of Chelsea died on January 18. He was in his sixty-first year.

Dr. Gilbert received his degree from Tufts College Medical School in 1914. He was a member of the staffs of the Chelsea Memorial Hospital and the Whidden Memorial Hospital in Everett and was a fellow of the American Medical Association.

His widow, his mother, a brother and two sisters survive.

**MASON**—Nathaniel R. Mason, M.D., formerly of Marblehead, died on May 6. He was in his seventy-third year.

Dr. Mason received his degree from Harvard Medical School in 1901. He was a fellow of the American College of Surgeons and a retired member of the Massachusetts Medical Society.

His widow survives.

**MCCREADY**—Leo T. McCready, M.D., of Jamaica Plain died on May 5. He was in his sixty-ninth year.

Dr. McCready received his degree from Tufts College Medical School in 1906. During World War II he was examining physician for the local Selective Service board.

Four sons and four daughters survive.

## MISCELLANY

### BOSTON MEDICAL HISTORY CLUB

The annual meeting of the Boston Medical History Club was held at the Boston Medical Library on May 18, 1948. The following officers were elected for the ensuing year: president, Dr. Reginald Fitz; vice president, Dr. John Fallon; and secretary-treasurer, Mr. James F. Ballard. Drs. Benjamin Spector, Madeline R. Brown, Harold Bowditch and Paul D. White and Mr. James F. Ballard were elected to the Council.

The principal speaker of the evening was Dr. Benjamin Spector, professor of anatomy and professor of the history of medicine, Tufts College Medical School. Dr. Spector discussed the work of the early pioneers in medicine in Italy from the time of the School of Salerno (about 1200) to Camillo Golgi (1844-1926), and its influence upon present-day medicine. The speaker pointed out the cosmopolitan character of the Salernum School and its work in anatomy, surgery, and medicine. He mentioned in particular the study of occupational diseases by Bernardino Ramazzini (1633-1714) of metabolism by Sanctus (1561-1636) and of epidemics by Fracastoro (1483-1553); the development of the theory of spontaneous generation by Francesco Redi, Lazzaro Spallanzani and Agostino Bassi (1626 to 1656); the early use of the microscope by Galileo (1564-1642) and Amici (1786-1863); the humanist anatomists, physicians and artists, Leonico de' Vio and Vesalius; and finally the work of the Nobel Prize winner Golgi on the nervous system.

Mr. James F. Ballard of the Boston Medical Library spoke briefly on three notable medical figures of the Italian Renaissance—Marsilio Ficino, Philippus Beroaldus and Hieronymus Cardanus—and demonstrated their works many of which were first editions.

In connection with Dr. Spector's address, selected works of the physicians discussed, as well as thirteenth century manuscripts of the Salernum period were shown.

## BOOK REVIEWS

*Nicolaus Pol Doctor 1494*. By Max H. Fisch, Ph.D. With a critical text of his *Gusac tract* edited with a translation by Dorothy M. Schullian, Ph.D. New York: Published for The Cleveland Medical Library Association by Herbert Reichner, 1947. 87 pp.

Nicolaus Pol, physician lived in the latter part of the fifteenth century and the early part of the sixteenth century. The date of his birth is unknown but it is assumed to have been about 1470 or a little earlier. He died in 1532. He was one of a group of famous physicians who collected comparatively large libraries for the period. Among those may be mentioned Ulrich Ellenbog, Hieronymus Munzer and Hartmann Schedel the author of the famous Nuremberg Chronicle.

E. P. Goldschmidt in 1938 published a monograph on the library of Hieronymus Munzer in which 185 titles are identified. (All the books and manuscripts were dated before the fifteenth century, except for two volumes printed in 1501 and 1503; this is easily understood since Munzer died in 1508.) Max Fisch in this study of the library of Nicolaus Pol has identified 467 titles. However, 186 were printed in the sixteenth century. The libraries of these physicians were generally scholarly in character, the number of strictly medical books being comparatively few except that of Pol. In which the number of medical and scientific incunabula number a hundred and thirty three, or 53 per cent of the total incunabula, or the basis of the Klebs census. Goldschmidt prefaces his description of the Munzer library with a scholarly life of Munzer. Likewise Fisch begins his book with a short biography of Pol. This is followed by a critical analysis of Pol's only published work, his tract on the gusac cure of syphilis, supplemented by a critical text edited from the manuscript in the Army Medical Library (about 1519) and the Venice edition (1535) with a page-by-page translation by Dorothy Schullian. The remainder of the volume is devoted to a description of the Pol books in the library of the Cleveland Medical Library Association and in the Historical Library of the Yale Medical School and to a list of identified Pol books. The Cleveland collection consists of thirty-eight titles of the fifteenth and two of the sixteenth century. Of the incunabula are medical, whereas the re-

(1935) and the old *B N A* (1895) nomenclatures. There is an excellent comprehensive index of subjects. The book is written for the student and practitioner and should prove useful to all German-reading physicians. It is recommended for all large medical libraries.

*Pediatric Progress Therapeutics of infancy and childhood*. Edited by Harry R. Litchfield, M.D., consultant in pediatrics, Rockaway Beach Hospital, New York City, attending pediatrician, Beth El Hospital, Brooklyn Women's Hospital and Brooklyn Thoracic Hospital, and chief in pediatrics, East New York Dispensary, Brooklyn, New York, and Leon H. Dembo, M.D., director of pediatrics, St. Ann's Hospital, visiting physician, St. Luke's Hospital, and consultant in pediatrics, Polyclinic Hospital, Cleveland, Ohio. 8°, cloth, 525 pp., with 47 illustrations. Philadelphia: F. A. Davis Company, 1948. \$8.00.

This annual, first published in 1947, is intended to supplement the comprehensive treatise, *Therapeutics of Infancy and Childhood*, published in 1947. The volume contains material of practical application and importance. It is the joint work of nineteen specialists. The following subjects are of special interest: use of the grid technic as a guide in the treatment of diseases causing growth failure in children, modern therapy of the dysenteries and salmonella infections, the use of thiourea drugs in hyperthyroidism, the Coburn treatment of rheumatic fever, the clinical use of normal human serum (gamma globulin), and antibiotic therapy. There is new material on viral hepatitis, toxoplasmosis, virus pneumonia, folic acid in anemia, therapy of allergic diseases and the Rh factor in therapeutics. A chapter on hernias in infants and children concludes the volume. There is a good index. The publishing is excellent in every way. The serial is recommended for all medical libraries and should prove valuable to pediatricians.

*The Practice of Group Therapy*. S. R. Slavson, editor. With a foreword by Nolan D. C. Lewis, M.D., 8°, cloth, 271 pp. New York: International Universities Press, 1947. \$5.00.

This book describes specifically the application of various types of group therapy to emotionally disturbed, socially maladjusted and mentally diseased patients as they are met with in the practice of psychiatry and psychotherapy. The work comprises thirteen papers by various authorities, and most of the chapters are based on papers presented at the conferences of the American Group Therapy Association held in 1945-1947. The text is divided into three parts: general principles, activity group therapy, and interview group therapy, sometimes called discussion therapy. A chapter on didactic group psychotherapy with psychotic patients is also included. Four chapters dealing with the actual treatment of cases are valuable in demonstrating the process employed in group therapy. The volume is well published in every way and should be in all psychiatric collections.

*Ulcer: The primary cause of gastric and duodenal ulcer. Diagnosis, medical and surgical treatment, prevention*. By Donald Cook, M.D., Chicago. 8°, cloth, 187 pp., with 27 illustrations. Chicago: Medical Center Foundation and Fund, 1946. \$6.00.

This short monograph discusses the various aspects of gastroduodenal ulcers.

*A Primer on Cardiology*. By George E. Burch, M.D., associate professor of medicine, Tulane University School of Medicine, senior visiting physician, Charity Hospital, consultant in cardiovascular diseases, Ochsner Clinic, and visiting physician, Touro Infirmary, New Orleans, and Paul Reaser, M.D., instructor in medicine, Tulane University School of Medicine, and assistant visiting physician, Charity Hospital, New Orleans. 8°, cloth, 272 pp., with 203 illustrations. Philadelphia: Lea and Febiger, 1947. \$4.50.

This manual, which is written primarily for the beginner in cardiology, emphasizes diagnosis. There is a chapter on the common heart diseases. An appendix includes the nomenclature and classification of heart disease of the New York and American Heart associations, cardiac measurements, diets and statistics of heart disease. The material is well arranged, and the text well written.

*Gynecological and Obstetrical Urology*. By Houston S. Everett, A.M., M.D., associate professor of gynecology, Johns Hopkins University School of Medicine, and associate in gynecology, University of Maryland School of Medicine, gynecologist and gynecologist in charge of the Cystoscopic Clinic, Johns Hopkins Hospital, visiting gynecologist, Church Home and Hospital, Hospital for the Women of Maryland and Union Memorial Hospital. Second edition. 8°, cloth, 539 pp. Baltimore: Williams and Wilkins Company, 1947. \$6.00.

In this second edition of a standard textbook, which was out of print a year and a half after publication of the first edition, the author has endeavored to bring the text and bibliographies up to date, but has not made any major additions to his text. A section on indirect cystoscopy has been added to the chapter on cystoscopy. The section on primary neoplasms of the bladder has been revised and a description of the Aldridge operation for stress incontinence has been added to the chapter on incontinence of urine. A good index concludes the volume. The book is well published in every way, and is recommended for all medical libraries.

## NOTICES

### ANNOUNCEMENTS

Dr. Daniel H. Hindman announces the removal of his office to 1093 Beacon Street, Brookline.

Dr. Samuel B. Kirkwood announces the removal of his office for the practice of obstetrics and gynecology to 1180 Beacon Street, Brookline.

Dr. Lucile Williamson announces the removal of her office from 412 Beacon Street to 399 Beacon Street, Boston, for the practice of pediatrics and allergic diseases.

### HARVARD SEMINAR ON HEALTH EDUCATION

The Massachusetts Department of Public Health, in cooperation with the Harvard Summer School of Arts and Sciences and of Education, is offering a four-week graduate seminar in health education from June 28 to July 23. The course is intended for school administrators, teachers of nutrition, social studies, health and physical education and agency personnel concerned with school health problems.

Mary E. Spencer, Ph.D., chief co-ordinator of public health education, Massachusetts Department of Public Health, has been appointed a member of the Harvard Summer School faculty to conduct the course. Visiting consultants will include physicians from the Massachusetts Department of Public Health, members of the staff of the Harvard School of Public Health and such outstanding authorities as John F. Conlin, M.D., M.P.H., director of medical information and education, Massachusetts Medical Society, C. Mayhew Derryberry, Ph.D., chief, Office of Health Education, United States Public Health Service, Charles C. Wilson, M.D., professor of public health, Yale University School of Medicine, W. W. Bauer, M.D., director of health education, American Medical Association, and C. E. Turner, Dr. P.H., assistant to the president, National Foundation for Infantile Paralysis.

Information regarding the seminar may be obtained from the director of the Harvard Summer School of Arts and Sciences and of Education, 9 Wadsworth House, Cambridge, and from the Massachusetts Department of Public Health, Room 524, State House, Boston.

The course will accommodate thirty students.

### TUFTS MEDICAL ALUMNI ASSOCIATION

The Tufts Medical Alumni Association will hold a dinner meeting in Chicago on Wednesday, June 23, at the Windermere East Hotel, 56th Street and Hyde Park Boulevard, Chicago. Dr. Harry A. Olin, of Chicago, is local chairman, and Dr. John F. Conlin is the Boston chairman of this event.

## OSTEOARTHRITIS OF THE CERVICODORSAL SPINE (RADICULITIS) SIMULATING CORONARY-ARTERY DISEASE

### Clinical and Roentgenologic Findings

DAVID DAVIS, M.D.,\* AND MAX RITVO, M.D.†

BOSTON

IN a previous report, attention was called to the occurrence of attacks of severe substernal and precordial pain in radiculitis of the dorsal spine.<sup>1</sup> In this communication, the clinical and roentgenologic findings are analyzed in a group of 43 patients with this condition. Although it has been established that pain in the shoulder girdle and anterior portion of the chest are often due to postural strain and hypertrophic arthritis of the spine, certain clinical aspects, such as the character and severity of the attacks, the occurrence of respiratory symptoms and the significance of parasternal tenderness, require further study and emphasis. Furthermore, although a few authors have discussed the roentgenologic findings in cervical radiculitis, there are few or no statistical data on the changes in the dorsal spine. This information was considered particularly important because radicular pain is frequently confused with that of coronary-artery origin. In fact, 23 of these 43 patients were thought to have coronary-artery disease or thrombosis before the diagnosis of radiculitis was established.

### CRITERIA FOR DIAGNOSIS

The diagnosis of radiculitis in each case was based on the presence of at least two of the following criteria: symptoms with definite radicular characteristics; reproduction of attacks by pressure over the spine, and prompt response to orthopedic therapy. The pain in the majority of cases presented the cardinal features of radiculitis—that is, attacks in bed at night, precipitation or aggravation of pain with changes in bodily position, as in stooping or turning in bed, and production or aggravation of pain by such acts as coughing, sneezing or straining at stool. Pain in the anterior portion of the chest was reproduced in 19 patients

during one or more examinations by pressure over the dorsal spine, and 9 additional patients experienced definite relief on hyperextension of the spine. The response to traction and other orthopedic measures was sufficiently striking in 28 cases to be of diagnostic significance. The history, physical examination and repeated electrocardiograms with six standard chest leads showed no evidence of coronary-artery disease in 37 cases. Six additional patients in the series had coexisting heart disease. These cases were included because the clinical evidence of radiculitis was incontrovertible.

### CLINICAL ASPECTS

Tables 1 and 2 summarize the clinical observations and roentgenologic findings in the cervical and dorsal spine in this group of 43 cases, which consisted of 32 male and 11 female patients, with an average age of fifty-two years. Although the patients were selected primarily on the basis of chest pain due to radiculitis of the dorsal spine, they were also studied for manifestations of cervical origin, such as shoulder-girdle pain, suboccipital headache, vertigo and spasm and tenderness of the posterior cervical muscles. Each patient was observed carefully over a period of weeks to months and, in some cases, years before the diagnosis of radiculitis was conclusively established.

The spinal nerves, composed of anterior and posterior roots, join just within the intervertebral foramina. Pain arising from irritation of the sensory roots is felt subjectively in or referred to the corresponding dermatomes represented by these nerves. The close similarity of the symptoms in radiculitis and coronary-artery disease is explained by the fact that the pain in both is dependent, at least in part, on afferent impulses from the same skin or muscle structures.<sup>2, 3</sup>

Phillips,<sup>4</sup> in 1927, called attention to the importance of examining the spine in thoracic and abdominal pain and showed that pain of this origin

could be mistaken for angina pectoris and gall-bladder and kidney disease. In the following year, Gunther, Sampson and Kerr<sup>5-7</sup> analyzed the cases of 50 patients whose chief complaint was pain in the anterior portion of the chest, often bilateral. The symptoms in their cases were generally mild and did not suggest pain of coronary-artery origin. In 1934 Nachlas<sup>8</sup> described 3 cases with pain in the anterior portion of the chest due to osteoarthritis of the spine simulating angina pectoris and coronary-artery disease. Later, Hanflig<sup>9,10</sup> dis-

picture was that of coronary thrombosis without evidence of infarction such as a subsequent rise in temperature, leukocytosis or alteration in the electrocardiogram. A few patients also experienced pain in the interscapular and axillary regions.

The majority had attacks while in bed at night, a well recognized characteristic of radicular pain. Eaton<sup>16</sup> suggests that this is probably related to an actual elongation of the spinal column that results after the reclining position has been maintained for several hours. He showed by roentgen-

cussed chest pain of radicular origin and stressed the diagnostic value of the response to orthopedic therapy. Further contributions to the subject were made by Oille,<sup>11</sup> Kelly,<sup>12</sup> Pawling<sup>13</sup> and Smith and Kountz.<sup>14</sup>

The most striking clinical finding in our patients was the occurrence of attacks of severe substernal or precordial pain, frequently radiating to the left upper extremity and occasionally to the neck and jaws and, in a few cases, accompanied by pallor and perspiration. The pain was almost always described as a pressure sensation, a heaviness or a vise-like constriction. In most cases the clinical

ologic studies before and after sleep that the height of the disks becomes significantly increased throughout the spine. In a few cases the attacks were almost exclusively nocturnal and, when bed rest was prescribed because of an erroneous diagnosis of coronary-artery disease, became more frequent and recurred during the day as well. One patient (Case 21) had eighteen severe attacks at night, but only three mild bouts during the day in a period of three months. Repeated attacks of substernal pain occurring mainly while the patient is recumbent should always raise the possibility of nerve-root origin.

A second cardinal feature of radicular pain is its relation to change in bodily position. The attacks in 33 patients had a close relation to prolonged sitting, particularly in a slouched position, and the chest pain was often relieved promptly on arising and walking about. Short bouts of pain occurred in 24 cases during such acts as bending, turning or getting out of bed. In prolonged coronary-artery pain, patients are commonly restless and not relieved in any position. In contrast several of these patients noted one or two positions that afforded

of walking, and a few were forced to slow down or stop, with some relief. In all but 3 cases, however, the attacks did not closely suggest the early stages of angina pectoris, seldom occurring exclusively in the course of walking. The pain was usually of longer duration, its onset often more gradual, and on resting the pain did not subside so quickly as that in angina pectoris. Most often there was a discrepancy between the number of attacks and the amount of walking or activity in general. For example, a patient might have many attacks in the

relief. A physician (Case 11) found comfort in repeated attacks when he assumed a stooped position or lay supine. Most patients were relieved on "straightening up" or on hyperextending the spine. One patient (Case 1) obtained relief by sitting up in bed and exercising the arms. Getting out of bed and walking about usually terminated or relieved the symptoms within a few minutes. A third cardinal feature, precipitation or aggravation of pain after coughing, sneezing, sighing, deep breathing or straining at stool, was noted in 8 cases.

Twenty-two of these patients had attacks of substernal or precordial pain at some time in the course

course of slow walking and never on climbing many flights of stairs. The relief obtained on resting in several cases was found to be closely related to a tendency of the patient unconsciously to assume a more erect posture and even to hyperextend the spine. One patient, a twenty-four-year-old woman (Case 27), had attacks closely simulating angina pectoris. Under observation she was seen to assume an exaggerated kyphotic position while walking. With the onset of substernal pain, she slowed down, stopped and unconsciously corrected her posture. Attacks could not be reproduced in this case or in

others by exercise-tolerance tests under standard conditions

During acute episodes, many patients complained of a peculiar respiratory distress. Although the patients described this as "shortness of breath," careful inquiry revealed that the symptom consisted of an inability to take a deep breath. Without a carefully taken history, this might easily have been misinterpreted as a manifestation of heart disease.

FIGURE 1 Lateral View of Cervical Spine

*There are spurs about the anterior and posterior margins of the fifth and sixth cervical vertebrae, with narrowing of the disk between these vertebrae. There is straightening of the cervical spine, with practically complete absence of the normal lordosis. There is osteoarthritis of the posterior intervertebral articulation between the fifth and sixth cervical vertebrae with narrowing and irregularity of outline of this articulation.*

Nineteen patients presented this complaint. In association with the restriction of respiration, breathing was rapid and shallow in a few cases. As inability to take a deep breath is a common psychosomatic complaint, the patients were studied carefully to exclude this possibility. In several cases the respiratory symptoms could be provoked by pressure over the dorsal spine; in a few, the symptoms occurred in attacks as the presenting complaint with little or no chest pain, simulating attacks of cardiac asthma.<sup>16</sup> The exact mechanism is not clear, but it is probable that, as in cervical radiculitis, motor paths are involved causing muscle spasm with inhibition of respiration.

The most significant diagnostic sign in radiculitis of the dorsal spine is the production of substernal or precordial pain on the application of pressure in the region of the spinous processes. Twenty-six patients showed marked local tenderness over the dorsal vertebrae, and firm pressure caused attacks in 19 of these on one or more occasions. The reproduced pain did not always correspond with the segmental distribution of the corresponding root. In Case 1, for example, precordial pain radiating along the fourth dorsal root could be elicited by pressure from the second to the seventh dorsal vertebra. This may be explained by the fact that pressure applied over one region of the spine may be transmitted and cause nerve-root irritation at a point some distance away. The reproduced pain in most cases was similar in character and distribution to that noted in the spontaneous attacks. When the patient assumed a hyperextended position, the attacks were difficult to elicit. In a few cases chest pain was also caused by forceful flexion of the head. According to Eaton,<sup>16</sup> this act results in upward displacement of the spinal cord with tension on the nerve roots, which are fixed in the extradural tissues.

An important manifestation of dorsal-nerve-root irritation is tenderness in the region of the costochondral junctions, a sign noted by Phillips<sup>4</sup> in 1927. Such tenderness, often marked, was found in 29 of 34 patients. It frequently occurred on both sides of the sternum. In several cases there was exquisite tenderness from the second to the fifth junction, although the fourth left junction was the most frequent site. In some cases it persisted long after the chest pain had subsided. The parasternal tenderness could usually be reduced or eliminated by traction applied to the cervical spine.<sup>17</sup> A study of controls showed that it was found comparatively infrequently in normal subjects without radicular symptoms.

In addition to chest pain, many patients had other manifestations of cervical radiculitis. This is to be expected, for osteoarthritis of the spine is often generalized. Nachlas,<sup>8</sup> Hanflig,<sup>9,10</sup> and Kelly<sup>12</sup> have called attention to the frequency of shoulder-girdle pain, and Kelly has stressed the occurrence of two less commonly appreciated symptoms: vertigo and suboccipital headache. Twenty-one patients complained of attacks of vertigo, 15 of suboccipital headache, and one or both were present in 11 cases. There was a higher incidence of other signs of cervical involvement, with limitation of neck rotation, palpable muscle spasm and tenderness in 24 cases.

#### ROENTGENOLOGIC ASPECTS

Any factor that produces narrowing of the intervertebral foramina may be responsible for nerve-root irritation. Osteophytes about the margins of the vertebrae, thinning of the intervertebral

disks, osteoarthritis of the posterior spinal articulations (Fig 1) and postural changes may diminish the size of the foramina. Spurs along the anterior borders of the vertebrae are usually not of great clinical significance. Osteophytes occurring at the posterior aspects of the vertebral bodies, however, are a frequent cause of radicular pain, since they are apt to encroach on the neural foramina (Fig. 2). Statements in the literature indicate that liping may be found in approximately 50 per cent of patients over fifty years of age. In Garvin's<sup>13</sup> series of 2090 patients, all of whom were over fifty years of age, there were hypertrophic changes in the lumbar spine in 67 per cent of the men and 40 per cent of the women. Cottrell<sup>10</sup> reported an incidence of

The intervertebral disks may become flattened and narrowed with consequent diminution of the spaces between the vertebrae due to various factors. As a result of trauma, the nucleus pulposus may be

FIGURE 2. Oblique View of Cervical Spine

There are hypertrophic spurs at the posterior aspects of the sixth and seventh cervical vertebrae with osteoarthritic changes involving the posterior spinal articulation between these vertebrae. The encroachment on the intervertebral foramen is clearly shown.

FIGURE 3. Oblique View of Cervicodorsal Spine

There is spurring in the lower cervical and dorsal regions. The disk between the fifth and sixth cervical vertebrae is narrowed. The posterior spinal articulation shows osteoarthritic changes. There is definite encroachment on the intervertebral foramen at this level. The cervical spine is straightened. There is increased kyphosis in the upper dorsal region.

herniated, the disk ruptured, or the cartilage injured. With advancing age or in consequence of occupational trauma, the intervertebral disks lose their elasticity and become flattened. Since the disk receives its blood supply from the adjacent bone, disease of the vertebral body eventually interferes with the nutrition of the disk and causes flattening. The disks have no power of regeneration, hence the changes once established are permanent. A close correlation between thinning of the intervertebral disks and radicular symptoms has been demonstrated. Oppenheimer<sup>20</sup> in a series of 200 apparently healthy persons found only 22 (11 per cent) with disk narrowing. On the other hand, in a series of 312 unselected cases of narrowed intervertebral disks, he reported clinical signs or symptoms pointing to a lesion of the involved spinal roots in 267 (85 per cent). Our patients, selected primarily because of chest pain, showed narrowing

55 per cent in a study of the thoracic and lumbar regions in 80 unselected ward cases with an average age of fifty-two years. Only 28 (33 per cent) showed slight to advanced thoracic-spine involvement and some had evidence of radiculitis. In contrast, about 95 per cent of our patients with similar average age showed spurring in the dorsal or cervical regions. Posterior marginal spurs occurred in the cervical spine in 23 (53 per cent) and in the dorsal region in 4 cases.

of the disks in 18 cases (42 per cent) in the cervical spine and in 7 cases (17 per cent) in the dorsal region. Of the 18 patients with cervical-disk narrowing, 17 had clinical evidence of cervical radiculitis.

Osteoarthritis of the intervertebral joints, usually associated with disk thinning, frequently results in narrowing of the apophyseal joints. In the early

loses its mobility. The degree of decalcification may serve in a general manner as a guide to the degree or duration of the process. Osteoporosis occurred in the cervical spine in 22 of our cases. In 9 of these, the changes were slight, in 13, they were moderate or marked. In the dorsal spine, there were 30 patients with bone atrophy, 17 with slight, 12 with moderate, and 1 with advanced changes.

One of the striking roentgenologic findings in our series was the high incidence of abnormal curvatures. Scoliosis is generally associated with rotations or lists causing strain of the ligaments, intervertebral disks and articulations. Disk narrowings and marginal osteophytes may occur in long-standing scoliosis.<sup>22</sup> The cervical spine, which normally presents a moderate lordosis, may become straight, less frequently more lordotic and rarely

FIGURE 4 *Lateral View of Dorsal Spine*

*There are spur formations about the margins of the vertebrae with slight narrowings of the intervertebral disks. The dorsal kyphosis is increased, and there is osteoporosis of the bones of the spine.*

stage, there is a strain on the capsule and ligaments, with periarticular soft-tissue reactions that may cause compression of the nerve roots; later, eburnation and exostosis formation develop. Joint abnormalities were noted in 20 per cent of Oppenheimer's<sup>20</sup> cases with disk thinning. Hadley<sup>21</sup> states that changes in the posterior articulations of the spine produced pain due to nerve-root compression in 72 per cent of his cases. Roentgenologic evidence of osteoarthritis of the intervertebral joints was present in the cervical spine in 11 (26 per cent) of our 43 patients; it was not noted in the thoracic spine. Narrowing or irregularity of intervertebral foramina from combined causes, such as disk narrowing, posterior marginal osteophytes and arthritis of the intervertebral joints, was demonstrated in the cervical spine in 26 patients (39 per cent) and in the dorsal spine in 10.

Osteoporosis, which is a manifestation of bone atrophy, occurs when the spine becomes rigid or

FIGURE 5 *Anteroposterior Projection of Dorsal Spine.*

*There are large osteophytes about the margins of the bodies of the dorsal vertebrae, with scoliosis in the upper and middle dorsal regions.*

kyphotic, and in the dorsal region, increased kyphosis is the rule (Fig. 3 and 4). Figure 5 shows scoliosis in the upper and middle-dorsal regions. In our patients, the most frequent finding in the cervical spine was straightening, which occurred in 23 cases; exaggeration of the normal anterior curvature was found in 5 and kyphosis in 1, and there was scoliosis to the right in 12 and to the left in 19. In the dorsal spine, kyphosis was increased in 23 cases, scoliosis occurred in 30—19 to the right and 11 to the left.

## DISCUSSION

The literature on radiculitis due to disease or injury of the vertebrae and protrusions of the intervertebral disks is vast, it is meager, however, on the subject of hypertrophic arthritis and postural strain. In consequence, the general practitioner has had little opportunity to become familiar with the clinical manifestations of this condition, and it is not generally appreciated how commonly pain in the anterior portion of the chest may be of spinal origin. The data presented above demonstrate that this pain may occur in the form of severe attacks closely simulating coronary-artery disease.

Coronary-artery disease and hypertrophic arthritis of the spine with radicular symptoms may coexist in the same patient, for both are common with advancing age. Six patients with previous myocardial infarcts or congestive failure had, in addition, unmistakable attacks of radiculitis, and 1 of these developed repeated attacks after being in bed for many days. It was first believed that these episodes were of coronary-artery origin, but further study revealed incontrovertible evidence of nerve root irritation. Only after bed boards and traction treatment had been applied did the attacks subside.

It is known that hypertrophic arthritis of the spine may be present without producing clinical manifestations. However, evidence has accumulated to show that it causes symptoms more frequently than is generally appreciated. Prior to the development of bony changes, soft-tissue reactions occur, and these are not demonstrable roentgenographically. The roentgenologic demonstration of osteoarthritis may be of great aid in establishing the diagnosis of radiculitis. This is particularly true when the symptoms are of short duration, the attacks cannot be reproduced, or the radicular characteristics of the pain are not clear-cut.

One of the striking findings in our study was the high incidence of osteoarthritis of the cervical spine. This may be considered an index of coexisting dorsal-spine involvement. The studies of Shore<sup>23</sup> also indicated that the incidence of intervertebral-joint arthritis was generally similar in the cervical and dorsal regions in 100 cases that came to autopsy. He further noted that the greatest occurrence of spinal arthritis was in the lumbar region, and that involvement higher up bore a constant relation to the curves and weight-bearing lines of the spine. This supports the concept that postural deviations play a direct role in the pathogenesis of intervertebral-joint arthritis. Seventeen of our patients gave a history of low-back pain, and all but 3 presented abnormalities of posture. The postural abnormalities were best demonstrated by roentgenologic — particularly in the cervical region. Examinations

of the entire spine may be helpful in the evaluation of the postural and arthritic problem.

If the possibility of radiculitis is borne in mind, the diagnosis can be made in most cases on the basis of a carefully taken history and the physical examination. The importance of recognizing radiculitis and differentiating it from coronary-artery disease cannot be overemphasized.

## CASE REPORTS

**CASE 1.** F. W., a 64-year-old dentist, was first examined by one of us (D. D.) on January 15, 1945. He gave a history of two episodes of prolonged substernal pain. The first, which had occurred 5 years previously had been accompanied by weakness and had persisted for several hours. The second 8 weeks prior to examination, had been similar but less severe. These attacks were not followed by a rise in temperature and three electrocardiograms taken after the second attack showed no evidence of coronary artery disease.

Physical examination of the heart was negative, except for a slight systolic murmur over the midsternum. The blood pressure was 175/110. An electrocardiogram was within normal limits. Two months later the patient complained of pain in the region of the dorsal spine which was worse at night and radiated to both sides of the chest. It was relieved by keeping the spine erect and was aggravated by stooping. There was marked tenderness over the tenth dorsal vertebra and pressure in this region caused acute pain radiating anteriorly. The blood pressure was 160/90. X-ray studies of the cervical spine showed anterior and posterior marginal osteophytes, disk narrowing, osteoarthritic changes in the fifth and sixth intervertebral joints and scoliosis. In the dorsal spine there were large osteophytes along the anterior margins of the third to ninth vertebrae.

One week later the patient experienced an attack of severe substernal pain while sitting in a theater. It began in the dorsal region and radiated to the anterior portion of the chest, where it was felt as a squeezing pressure sensation. He recognized it as similar to the distress noted 5 years previously. It was severer than the earlier attacks and required morphine for relief. On examination the heart and lungs were normal. Moderate pressure over the sixth and seventh dorsal vertebrae precipitated severe pain, which radiated around the chest wall to the substernal region. The pain was elicited with difficulty when the patient stood erect or hyperextended the spine. The response to orthopedic treatment was prompt. On several occasions during the following year he experienced substernal constriction on stooping and occasional mild pain in the right shoulder region. On several examinations, tenderness was present in the region of the second to fifth left costochondral junctions. The posterior cervical muscles were spastic, and neck rotation was limited. On two occasions the patient had attacks of persistent vertigo aggravated by bending or moving the head from side to side and relieved promptly by traction therapy.

**CASE 2.** I. B., a 36-year-old man, was seen on April 20, 1946, complaining of attacks of severe substernal pain and pain in the left side of the chest of 5 weeks duration. The pain started in the interscapular region and radiated to the midportion of the sternum and precordium. On several occasions it awakened him at night and was present in the morning just after he got out of bed. Recently, the pain had recurred intermittently during the day and the nocturnal attacks had become more pronounced. Pain was brought on or aggravated by bending, prolonged sitting, deep inspiration, or coughing. A week previously the patient had had a severe attack after lifting a heavy weight. It had started as a "cramp" between the shoulder blades localized in the region of the anterior midportion of the chest, and had lasted for about 10 minutes. Two days later it recurred with greater severity while he was walking cannot stop. After some time he slowly made his way to the office. He was pale and in obvious distress. He tried to catch his breath and stated that his "wind" The respiratory disturbance and substernal pain recurred intermittently for several hours.

Examination of the heart and lungs revealed no abnormalities. The blood pressure was 130/90. There was marked spasm of the posterior cervical muscles, with limitation of head rotation and a moderate kyphosis of the upper dorsal spine. There was localized tenderness over the seventh and eighth dorsal vertebrae, and firm pressure caused substernal and precordial distress similar to that in the spontaneous attack. Simultaneously, the breathing became rapid and shallow. An electrocardiogram with six standard chest leads was within normal limits.

Roentgenologic examination showed slight osteophytic changes in the cervical and dorsal regions and pronounced postural changes. There were scoliosis and straightening in the cervical region and dorsal kyphosis. The response to orthopedic treatment was dramatic, with complete disappearance of symptoms, which have not recurred during the past 2 years.

### SUMMARY

The clinical and roentgenologic findings in 43 patients complaining of attacks of substernal or precordial pain of nerve-root origin (radiculitis) are analyzed. The location, character and radiation of the pain closely simulated coronary-artery disease.

The diagnosis of radiculitis was based on at least two of the following attacks of pain in bed, with change in bodily positions, and on coughing, sneezing or straining at stool, reproduction of the attacks by pressure over the dorsal spine and a striking response to orthopedic therapy.

In addition to the generally recognized features of dorsal-spine radiculitis, particular attention is called to the occurrence of a peculiar respiratory distress of radicular origin that may easily be mistaken for a manifestation of heart disease. The value of parasternal tenderness as a sign of dorsal-root irritation is also emphasized.

The patients, in addition to irritation of the dorsal nerve root, showed a high incidence of symptoms and signs of cervical radiculitis, such as shoulder-girdle pain, suboccipital headaches, vertigo, muscle spasm, tenderness and limitation of neck rotation.

Roentgenologic examination of the dorsal and cervical spine showed a high incidence of postural and osteoarthritic changes. The changes in the cervical spine may be summarized as follows: disk narrowings, 18 cases, anterior osteophytes, 39 cases, posterior osteophytes, 23 cases, osteoarthritis of the intervertebral joints, 11 cases, scoliosis, 31 cases, straightening, 23 cases, increased lordosis, 5 cases, kyphosis, 1 case, and osteoporosis, 22 cases.

In the dorsal spine, there was disk narrowing in 7, anterior osteophytes in 39, posterior osteophytes in 4 and scoliosis in 30 cases.

The roentgenologic findings demonstrate the location, nature and extent of the osteoarthritic changes in the spine and are of some value to the clinician when the symptoms are of short duration, the attacks cannot be reproduced or the radicular characteristics are not clear.

The recognition of radiculitis and its differentiation from coronary-artery disease are of practical importance in therapy and prognosis.

## UTERINE CANCER ITS EARLY DETECTION BY SIMPLE SCREENING METHODS\*

DANIEL J. MCSWEENEY, M.D.,† AND DONALD G. MCKAY, M.D.‡

BOSTON

UNTIL the cause of and a specific cure for cancer have been found, successful treatment must depend on early diagnosis. Since symptoms suggestive of cancer may not appear until the disease is well advanced, early diagnosis must be made by a process of "screening" whereby symptom-free persons are examined at frequent intervals and studies made to detect malignant lesions.

The most frequent cancers in women are those of the uterus, both cervix and corpus, which comprise about 30 per cent of all malignant tumors in women, lesions of the cervix predominating over those of the corpus about 5:1. Early malignant lesions of the uterus are readily amenable to treatment, and five-year survival rates of 100 per cent may be expected if the cases are treated sufficiently early. Fortunately, the uterus, especially the cervix, offers opportunity for "screening" and the diagnosis of early lesions with very little inconvenience and expense to the patient.

A year ago we started a clinic for the early detection of cancer of the uterus at the Boston City Hospital. All the departments of the hospital have been requested to refer as many women over thirty-five years of age as possible to the Gynecological Clinic for "screening." This consists of a careful gynecologic history, with special attention to abnormal bleeding and vaginal discharges, a pelvic examination, a speculum examination and a vaginal smear. The last is most valuable as a test to determine cases that may require diagnostic curettage or cervical biopsy, not otherwise indicated by the history and pelvic examination. Cases that are positive on smear, or suspicious on smear, history or pelvic examination are subjected to biopsy by curettage or cervical biopsy, or both. If either of these procedures is positive the patient is referred to the Tumor Clinic for treatment. We never institute treatment on the evidence of a positive smear alone. If the case is suspicious but with a negative biopsy the patient is seen at least once a month in our special clinic, where more smears and possibly more biopsies are taken. In all obviously negative cases the patients are seen every six months for re-examination. In addition, one of the major interests in this study was to determine whether or not unsuspected cases of carcinoma could actually be detected by the vaginal smear.

## TECHNIC

The vaginal smear for the diagnosis of cancer of the uterus was introduced by Papanicolaou in 1928. Its value is based on the fact that carcinomatous lesions of the cervix and endometrium are exfoliative. The cancer cells are shed and collect in a pool in the posterior fornix together with cells from the endometrium, cervix and vaginal mucosa. Material for the smear is obtained by aspiration with a slightly bent, hollow glass tube of small caliber at one end of which is a rubber bulb. The glass tube must be absolutely dry. No douche or lubricant should be used prior to the taking of the smear. The tube with the rubber bulb compressed is inserted high into the posterior fornix and moved from side to side as the pressure on the bulb is released. The fluid thus obtained is blown onto a clean glass slide and smeared quickly, and the slide is immediately dropped into equal parts of 95 per cent alcohol and ether for fixation for at least thirty minutes. Care must be taken that the smear does not dry. Smears may be kept in the fixative for as long as two weeks before staining. The staining is done by the Papanicolaou technic, which is particularly adapted for delineating nuclear detail. For the most part only one smear was made in each case, but in many cases two or three were made.

## CYTOLOGY

The cellular characteristics of the vaginal smear, which have been extensively described by several authors,<sup>1-3</sup> are not dealt with in great detail. However, a brief description is in order for the purposes of this paper.

To recognize the abnormal cells in a smear it is essential to know the appearance of the normal cells. The most prominent of the normal cells are the large pavement-like cells that are desquamated from the superficial layers of the stratified squamous epithelium of the vagina and cervix. They are characterized by a small nucleus, an abundant cytoplasm and an irregular angular cytoplasmic edge. The cornified type of superficial cell has a pink cytoplasm and a pyknotic nucleus. The less common precornified type has a blue-green cytoplasm and a somewhat larger nucleus.

The basal-type cell which is derived from the deeper layers of the epithelium is a smaller round cell with green-staining cytoplasm and a relatively larger nucleus in proportion to the amount of cytoplasm. These cells are seen most frequently in postmenopausal patients but may be found in any smear.

\*From the Department of Obstetrics and Gynecology, Boston City Hospital and Boston University School of Medicine, and from the Malloy Institute of Pathology, Boston City Hospital.  
This study was aided by a grant from the American Cancer Society, Inc. (Massachusetts Division).

†Clinical professor of obstetrics, Boston University School of Medicine.  
‡Instructor in pathology, Boston University School of Medicine and in pathology, Malloy Institute of Pathology.

Very rarely does one find a smear that does not contain polymorphonuclear leukocytes, and these are readily recognized as small round cells with lobulated nuclei and a pale-green cytoplasm.

Red cells are often present in negative as well as in positive smears. Meigs et al.<sup>2</sup> state that red cells or red-cell debris is always found in positive smears and that the diagnosis of cancer is never made without some evidence of blood.

Histiocytes are found in negative and positive smears, more often in the latter. The nucleus is round or ovoid and contains finely stippled chromatin. The cytoplasm may be relatively scant but usually is abundant and filled with phagocytized debris such as red cells, fat vacuoles or polymorphonuclear leukocytes. They are sometimes difficult to distinguish from malignant cells since some malignant cells have phagocytic properties. The major feature in distinguishing these two cell types lies in the difference in the nuclei.

Benign giant cells are occasionally found, and these are large multinucleated cells with the nuclei located at the periphery of the cytoplasm. The nuclei have finely stippled chromatin and show little variation in size or shape.

Endometrial cells usually occur in small and large groups. They have round or ovoid regular nuclei with a finely granular nucleoplasm and a very scant amount of cytoplasm. They are found frequently during the later stages of menstruation, and in some cases these normal endometrial cells are seen in adenocarcinoma of the uterine body. Therefore, the presence of endometrial cells as well as red cells should arouse suspicion, and if no tumor cells are present on the smear, repeat smears should be done.

The diagnosis of cancer is almost entirely based upon nuclear changes. The cytoplasmic stain is extremely variable. Some tumor cells have green cytoplasm, whereas others have a bright-red cytoplasm.

These cells possess several features that stamp them as malignant cells. The nuclei are large in proportion to the amount of cytoplasm, in some cases no cytoplasm is visible. The nuclei may contain a large prominent nucleolus, or the chromatin may be distributed in coarse clumps. The nuclear edges may be wrinkled and folded, and the nucleus may appear as one solid, purple mass. When groups of cells occur together the extreme variation in the size and shape of the nuclei is readily demonstrated. Another point that aids in recognition of tumor cells is the fact that the cytoplasmic borders are indistinct and hazy. This is in contradistinction to most clusters of normal cells.

A few distinct types of cells are recognizable and are almost pathognomonic of cancer. The so-called "tadpole cell" is one of these. It has a rounded mass of cytoplasm which contains the nucleus, and a long cytoplasmic tail, which gives it the appearance of a tadpole. This cell is found in squamous-cell

carcinoma of the cervix. Another distinctive cell is the "spindle cell," which has the shape of a fibrocyte, with an elongated nucleus, and long thin spindles of cytoplasm on either side of the nucleus. This cell is a modified epithelial cell and is also seen in squamous-cell carcinoma of the cervix.

Tumor giant cells contain several large nuclei, which vary in size and shape and which are usually in the central portion of the cell. The nuclear differences distinguish them from the multinucleated giant cells of inflammatory origin.

Mitotic figures are rarely encountered. During the course of this study, none were seen. Papanicolaou and Traut<sup>4</sup> have had a similar experience and point out that, since the cells found in vaginal fluid are dead and desquamated, one would not expect to find mitotic figures in the smear.

The majority of smears from patients with carcinoma contained numerous malignant cells, many in groups, and were therefore not difficult to diagnose. On the other hand, a few were extremely difficult to diagnose because only one or two malignant cells were present. In 1 case a positive diagnosis was made upon the finding of one tadpole cell. Red cells and histiocytes were also present on the smear. In another case the diagnosis was made by the presence of one spindle cell. Both diagnoses were confirmed by biopsy and serve to illustrate the paucity of malignant cells in some positive smears.

## RESULTS

Many obvious cases of cancer were included in the study to demonstrate the various types of cancer cells and to provide definitely positive smears for comparison with questionable smears in which the exfoliated cells were few in number. In the 639 cases 934 slides were examined, and 357 biopsies were performed. The number of cases of carcinoma determined by biopsy was 54, including 43 cases of epidermoid carcinoma of the cervix, 2 of adenocarcinoma of the cervix and 9 of adenocarcinoma of the corpus uteri. The number of cases of carcinoma with positive smears was 51, and false-negative smears (negative smear, positive biopsy) were noted in 3 cases. The number of cases with negative smears was 585, with false-positive smears (positive smear and negative biopsy) in 12 cases. There were 42 cases of clinically obvious carcinoma, 6 cases of suspected carcinoma confirmed by biopsy and smear simultaneously and 6 cases of carcinoma unsuspected clinically, diagnosed primarily by vaginal smear and subsequently confirmed by biopsy.

Of 54 cases of carcinoma of the uterus a positive vaginal smear was obtained in 51—an accuracy of 95 per cent. Two of the patients from whom a false-negative smear was obtained had vesicovaginal fistulas, and there were very few cells on the slides. The other patient was bleeding, and the blood diluted the vaginal fluid to such an extent that erythrocytes and polymorphonuclear leukocytes were

the only cells seen. These three cases were all examples of far-advanced carcinoma. Fortunately, it is in the clinically obvious cases of carcinoma that the smears may be incorrectly regarded as negative and usually not in the cases of early carcinoma.

Of the 585 patients demonstrated not to have cancer a correct negative diagnosis was made in all except 12. These 12 cases constitute the false-positive group. This is 2 per cent of the cases diagnosed negative by smear and 4 per cent of the 303 cases proved negative by biopsy. This is a low percentage of error, but the fact that a false-positive diagnosis is made at all restrains one from undertaking therapy on the basis of the smear alone. No treatment has been instituted in this clinic without a positive biopsy.

One of the most interesting features of this study was the fact that 6 cases of carcinoma were diagnosed primarily by vaginal smear. An additional case of this type has recently been examined in this clinic and serves to illustrate the usefulness of the vaginal smear. The patient was a twenty-seven-year-old

FIGURE 1. Smear in Case 3 Showing a Group of Three Malignant Cells ( $\times 250$ )

woman who entered the clinic in January, 1947, when a smear and biopsy were taken. The smear was diagnosed positive and a tentative diagnosis of carcinoma in situ was suggested. However, the biopsy revealed a condyloma acuminatum. This smear was considered to fall in the false-positive group. The condyloma was treated, and the patient sent home. In October, 1947, the patient again entered the clinic, and another smear was taken but no biopsy was done. The smear was diagnosed positive, and showed many more tumor cells than the smear taken in January. The patient was brought back to the hospital and a biopsy done. The pathological diagnosis of the tissue was carcinoma in situ.

The following brief abstracts are typical of cases in this group. In Cases 3, 4, 5, 6, 7 and 12 the diagnosis was made primarily on the basis of the vaginal smear.

CASE 1. L. S. (B.C.H. 619 350), a 42-year-old woman, had had a supravaginal hysterectomy 14 years previously. There had been slight bleeding for 2 weeks. A small 1-cm erosion of the cervix was present. A vaginal smear was positive. A cervical biopsy showed epidermoid carcinoma.

CASE 2. M. M. (B.C.H. 785 292), a 58-year-old woman, had been treated for carcinoma of the cervix by radium and x-ray therapy in another hospital in 1940. No pain or bleeding had subsequently occurred. An irregular, pinched-out

FIGURE 2. Smear in a Case of Epidermoid Carcinoma of the Cervix Showing Tadpole Cells ( $\times 250$ )

area was seen on the left side of the cervix. A vaginal smear was positive. Biopsy showed epidermoid carcinoma.

CASE 3. M. K. (B.C.H. 546,329), a 71-year-old woman had no symptoms. A routine vaginal smear was positive (Fig. 1). Cervical biopsy showed epidermoid carcinoma.

CASE 4. B. C. (B.C.H. 555,284), a 76-year-old woman had had slight bleeding for 1 month. The cervix appeared normal. The uterus was small and regular in contour. A smear was positive. Uterine curettings showed adenocarcinoma.

CASE 5. A. B. (B.C.H. 699 977), a 43-year-old woman, had had a supravaginal hysterectomy for fibroids. At follow-up examination in the outpatient department a routine vaginal smear was taken. The smear was positive (Fig. 2). Biopsy of the cervix showed epidermoid carcinoma.

CASE 6. A. W. (B.C.H. 811 599), a 76-year-old woman, on August 3, 1946, had a diagnostic curettage and cervical biopsy because of bleeding. No carcinoma was found. On October 23 a vaginal smear was positive. Repeated curettings showed adenocarcinoma.

CASE 7. E. O. (B.C.H. 804 661), a 47-year-old woman had had a total hysterectomy for adenocarcinoma of the corpus uteri in October 1945. This had been followed by twenty x-ray treatments. There were no symptoms. A vaginal smear on August 7, 1946, was positive. Careful examination revealed a 0.5-cm. excavation at the right lateral angle of the scar in the vaginal vault. The first two biopsies from this area were negative for carcinoma, but the smears continued to show cancer cells. A third biopsy showed two small foci of carcinoma in lymphatic vessels.

CASE 8 R M (BCH 776,863), a 43-year-old woman, had menopausal menorrhagia. A smear was positive. Diagnostic curettage showed hyperplasia of the endometrium,

FIGURE 3 Section of Tissue in Case 10

Note the desquamated portion of the tumor lying in the gland-like space in this adenocarcinoma (x150)

with an area of squamous metaplasia to be regarded as potentially malignant

CASE 9 D G (BCH 1,222,039), a 50-year-old woman, had a positive routine smear. Biopsy of the cervix and curettings were reported as showing chronic cervicitis, the

FIGURE 4 Smear in Case 10, Showing a Group of Malignant Cells (x250)

endometrium revealed inflammation with areas of markedly atypical squamous metaplasia of epithelium, which suggested early carcinoma

CASE 10 G D (BCH 1,214,073), a 51-year-old woman, had no symptoms. A routine smear was positive, and curettings showed well differentiated adenocarcinoma (Fig 3 and 4)

CASE 11 L J (BCH 849,782), a 29-year-old woman, complained of intermenstrual bleeding for 2 months. Two years previously she had been told that she had an erosion of the cervix but had received no treatment. The vaginal smear was positive. There was a 1-cm area of ulceration on the left lateral aspect of the external os. Biopsy showed epidermoid carcinoma of the cervix

CASE 12 M F (BCH 943,129), a 35-year-old woman, gave a typical history of endometriosis, and the diagnosis was confirmed by operation. There had been no abnormal vaginal bleeding. A routine smear prior to operation was positive. Speculum examination revealed a small, reddish area on the posterior vaginal wall at the junction of the portio with the vaginal mucosa. Biopsy from this area was reported as showing epidermoid carcinoma

## DISCUSSION

From our experience we believe that this method of screening is simple and efficient and definitely aids in the diagnosis of carcinoma. The degree of accuracy, of course, depends on the care with which the smears are taken and the training and experience of the cytologist. Although errors are made and the smear technic should never supplant meticulous biopsy, nevertheless, as Gates and Warren<sup>3</sup> aptly state in their excellent treatise on the subject, "The thing that matters primarily is whether the use of the method will discover cancer and initiate treatment earlier than would otherwise be done." In our series we have encountered 6 cases of carcinoma that we believe would have been treated at a much later date if the vaginal smear had not been used. In addition, 6 cases of carcinoma were diagnosed by the ordinary methods of examination as a result of the establishment of this clinic

## SUMMARY

A screening clinic for the detection of early carcinoma of the uterus is described, with especial emphasis on the vaginal smear

In one year 639 cases were examined, and 934 smears studied

Of 54 cases of cancer, 51 were diagnosed correctly by smear

Six cases of carcinoma, which might otherwise have been neglected, were detected by the vaginal-smear technic, and 6 others were detected simultaneously by biopsy and smear.

## BRILL'S DISEASE\*

## Report of Two Serologically Proved Cases of Typhus Fever in Irish-Born Residents of Boston

HERBERT R. MORGAN, M.D.,† FRANKLIN A. NEVA, M.D.,‡ ROBERT J. FAHEY, M.D.,§  
AND MAXWELL FINLAND, M.D.¶

## BOSTON

THE name Brill's disease is usually given to the isolated cases of typhus fever that occur in the coastal towns of the northeastern United States.<sup>1</sup> In 1934 Zinsser<sup>2</sup> showed that these cases develop almost exclusively in immigrants from areas where there have been epidemics of louse-borne typhus fever. He demonstrated that the rickettsias that he was able to isolate from a few of these patients resembled the causative agent of epidemic or louse-borne typhus fever but that the disease was not associated with louse infestation. He came to the conclusion that Brill's disease represented a recrudescence of a latent infection of louse-borne typhus acquired while the patient had lived in an area where the disease occurred. Recently, Plotz<sup>3</sup> has presented serologic studies on several cases in Jewish immigrants that support this concept.

In Zinsser's<sup>2</sup> series of over 500 cases about 80 per cent were in Russian-Jewish immigrants, whereas only 4 cases were reported in persons from Ireland. The diagnoses in most of these cases were made on clinical grounds alone.

Two cases of Brill's disease in Irish-born Americans who have lived in Boston for many years are presented below, with serologic evidence that their illness was due to an infection with the causative agent of epidemic or louse-borne typhus fever. These two cases are of additional interest since the clinical findings were consistent with a diagnosis of primary atypical ("viral") pneumonia until the appearance of the rash.

## CASE REPORTS

**CASE 1.** C. C., a 56-year-old longshoreman had felt perfectly well until September 8, 1946, when he became weak and dizzy while unloading cargo from Chile. On the next day he had a shaking chill followed by a frontal headache. On September 10, when he was seen by a physician, the temperature was 104°F. He continued to have chills and chilly sensations and a marked feeling of malaise until he entered the hospital on September 14.

The patient had been born in Galway, Ireland and had come to Boston in 1910 at the age of 20. He had not left this area during the past 20 years. He denied any serious childhood illness to Ireland and could not remember any febrile illness in his family associated with a rash. He had been

treated in this hospital in 1914 for "blood poisoning" following an infection of his right hand.

Physical examination revealed a patient who appeared flushed and somewhat somnolent and who complained of severe headache. The skin was warm, dry and free of any eruption. The sclerae and conjunctivae were injected and slightly icteric. Examination of the chest revealed slight dullness to percussion over the right lower lung posteriorly and some slightly decreased breath sounds over this area. The findings in the heart and abdomen were within normal limits.

The temperature was 104°F by rectum, the pulse 98, and the respirations 26. The blood pressure was 134/60.

On the 20d hospital day, the patient developed a rash consisting of small, red maculopapular lesions on the chest and back with a few lesions on the upper arms. These faded gradually during the next 4 to 5 days. The temperature remained elevated to about 104°F until September 19. During that time the patient continued to be somewhat somnolent and lethargic and exhibited twitching of the arms and hands and facial grimaces. Treatment consisted of about 4500 cc. of fluids daily during the febrile period and, beginning on September 17, 30,000 units of penicillin intramuscularly every 3 hours for 11 days. On September 19 the temperature began to fall, reaching normal levels on September 23. During that time the patient showed marked subjective improvement. He was discharged on October 3.

On admission the urine had a specific gravity of 1.008 and gave a + test for albumin and a positive test for bile. The blood hemoglobin was 94 per cent, and the white-cell count 6650 with 81 per cent neutrophils, 14 per cent lymphocytes and 5 per cent monocytes. The white-cell count was 10,000 on September 16 and then returned to normal. The initial icteric index was 25, and this decreased to 10 by September 18. The blood ooprotein nitrogen was 42 mg per 100 cc. and fell to 25 mg by September 18. The serum cephalin flocculation was ++, the prothrombin time was 85 per cent of normal and the formal-gel test was negative. Lumbar puncture showed a clear spinal fluid with 3 or 4 lymphocytes and 3 erythrocytes per cubic millimeter and a total protein of 11 mg per 100 cc. Several blood cultures showed no growth. Cultures of the first specimen of urine yielded *Pseudomonas aeruginosa* and *Escherichia coli*, but subsequent ones were negative. An electrocardiogram on September 20 showed a normal sinus rhythm with a partial auriculoventricular block, the PR interval being 0.23 second, another tracing 6 days later disclosed a PR interval of 0.20 second. X-ray films of the chest taken at the time of entry and again 3 days later revealed areas of diffuse, finely mottled density in both lower lungs and in the right middle-lung field consistent with primary atypical pneumonia. Another film taken 8 days later showed clear lung fields.

Agglutination tests with organisms of the typhoid Salmonella group *Brucella abortus* and *Pasteurella tularensis* were negative. Cold hemagglutination and heterophil antibody tests were also negative. Complement fixation tests with the antigen of Rocky Mountain spotted fever and agglutination tests with *Proteus vulgaris* strains OX2 and OXK were negative. The results of the Weil-Felix test (agglutination of *P. vulgaris* strain OX19) and of tests for antibodies against the rickettsias of epidemic and murine typhus are shown in Figure 1.

**CASE 2.** S. E., a 51-year-old laborer, entered the hospital on October 2, 1947. He had been entirely well until September 29 when he had caught cold. That evening he felt weak and nauseated and went to bed without eating. During the night he had repeated shaking chills followed by drenching sweats. Later he developed a dry, hacking cough which occurred hourly in paroxysms lasting 5 to 10 minutes. On

the appearance of the rash, the character and distribution of which suggested the possibility of a rickettsial disease. Since the rash in Brill's disease is frequently absent or consists only of a few macules, the diagnosis might easily have been missed.

The diagnosis of a rickettsial infection was made by serologic methods. The rising titer of agglutinins for *P. vulgaris* (strain OX19) was consistent with a diagnosis of typhus fever. Endemic or murine typhus could not be ruled out in these cases on clinical or epidemiologic grounds. Epidemic or louse-borne typhus does not occur in this area since living conditions in general do not provide a louse-infested population, which is necessary for its spread and maintenance. Furthermore, if louse infestation were a factor, other cases from the same home might be expected. Since both patients had been born in Ireland, where epidemic typhus has occurred, they were thought probably to have Brill's disease.

In both cases, the fact that the patients spent considerable time on the docks raised the question of possible infection from a shipboard source. This was particularly true of the patient in Case 1, who had been unloading cargo from Chile at about the time he became ill. Murine typhus was considered as a possible diagnosis, but the incubation period would then have been very short if the disease had been acquired from rats on this ship. However, on close questioning both patients were discovered to have come to the United States from County Galway, Ireland, where louse-borne typhus is known to occur. This area was the site of a serious epidemic in 1903-1905,<sup>4</sup> and an outbreak of over 134 cases occurred there as recently as 1942. The typhus epidemic of 1903 occurred when the patients were thirteen and seven years of age, respectively. Since typhus fever is often a mild disease in childhood, both patients could have been infected during this outbreak without an illness of such severity as to be readily remembered.

In both patients, the clinical course of the disease was consistent with that seen in Brill's disease. The low initial white-cell counts, which rose to 10,000 or more during the second week, are frequently observed in such cases. The development of thrombophlebitis as a complication in Case 2 was of particular interest since patients with typhus fever often develop thromboses of blood vessels.

The suspicion that these patients were having a recrudescence of a previous attack of louse-borne typhus fever was confirmed by the rickettsial serologic studies noted in Figures 1 and 2. The rickettsial complement-fixation tests gave consistently higher titers with the epidemic antigen as compared with those obtained with the murine antigen. This difference is considered to be diagnostic of epidemic typhus fever.\* In most cases, the rickettsial agglutination tests showed similar differences in

titers. The difference in titers was still demonstrable in Case 1 a month and again eleven months after the illness, and in Case 2 the difference was observed two months after the acute disease. Neither of these patients had received any typhus vaccines. The findings seem to rule out the possibility that the high titer to the epidemic antigen was due to the fact that these patients had had epidemic typhus fever as children with a marked rise in antibody titer for this antigen as an anamnestic reaction during an attack of murine typhus. If that had occurred, one would have expected the epidemic titer to fall off more rapidly. In these patients, the rickettsial agglutination tests seemed to show less specificity with most serum specimens than the complement-fixation tests.

The Weil-Felix agglutination tests in both patients are consistent with a diagnosis of typhus fever in that the titers with *P. vulgaris*, strain OX19, show a rise in titer, whereas there are no significant titers with strain OX2 or OXK. It is of interest that in Case 1, in which a titer of agglutinins of 1:2560 for strain OX19 developed during the course of the illness, these agglutinins were easily detectable almost a year later, whereas the titer in Case 2 fell rapidly during convalescence. The negative results in the complement-fixation tests for Rocky Mountain spotted fever in Case 1 and for Q fever, rickettsialpox and psittacosis in Case 2 eliminate them as possible diagnoses.

It appears most likely, therefore, that the illness in these cases was Brill's disease—the recrudescence form of epidemic typhus fever—occurring as a sequel to an attack of typhus fever during childhood in Galway, Ireland.

The diagnosis of Brill's disease should be considered in any foreign-born American regardless of race, who comes from an area where epidemic typhus occurs and who suffers from an acute febrile illness characterized by severe headache, chills and fever with or without a skin rash.

#### SUMMARY

Two cases of Brill's disease occurring in Irish-born persons who had lived in Boston for many years are described. The clinical features were consistent with the diagnosis of primary atypical (viral) pneumonia until the appearance of the rash, which was characteristic of that seen in rickettsial infections. The diagnosis of the recrudescence form of epidemic or louse-borne typhus fever was established by serologic methods.

## THE USE OF BENADRYL IN PARKINSON'S DISEASE

## A Preliminary Report of 8 Cases

JOSEPH BUDNITZ, M D \*

PITTSFIELD, MASSACHUSETTS

**P**ARALYSIS agitans, or Parkinson's disease, is a chronic progressive disease of the corpus striatum and extrapyramidal motor system for which there is no known cure. Treatment has always been symptomatic, and useful drugs have been limited almost entirely to those in the atropine series. These have consisted of hyoscine, hyoscyamine, belladonna and stramonium, either individually or in various combinations. Amphetamine (benzedrine) sulfate has occasionally been beneficial in relieving some of the symptoms, but its mechanism of action has never been clearly explained.

The use of benadryl in paralysis agitans was first tried on a patient in September, 1946, on a purely empirical basis. The result was so gratifying that other subjects with paralysis agitans were also given the drug to determine whether the improvement noted in the first patient was simply an unusual response in a suggestive person or whether the reaction could be consistently reproduced in others. There is no literature on the use of benadryl in paralysis agitans, but McGavack, Elias and Boyd<sup>1</sup> mentioned its use in 4 patients, with improvement in 3.

## CASE REPORTS

**CASE 1** J C, a 57-year-old man, had been suffering from Parkinson's disease for 14 years. He had a typical mask-like face and a pill-rolling tremor of the fingers. The voice was high pitched and thin. He stood with the knees bent and the back stooped forward. He could walk only a few steps before starting to run to maintain balance. Even then he could go only about 10 yards before he clutched at any object in his path to keep from falling. There was no past history of encephalitis.

The patient was in the hospital for 5 months and obtained the usual slight benefit derived from stramonium and scopolamine. On September 24, 1946, the scopolamine was discontinued and 50 mg of benadryl four times daily was begun. In a few days marked improvement was noted. The patient volunteered the statements that he was walking better, swallowing was easier, he was less nervous and shaky, the legs felt stronger and drooling from the mouth had stopped. Several independent observers in the ward noted that he could walk a much greater distance before he started running, and that he could stop himself at any time without the need of supporting himself on some object in his path.

On October 4 the amount of benadryl was doubled, and the stramonium was discontinued so that the patient received nothing but benadryl. With the increase of benadryl dosage, a pounding and humming in the ears, but no further improvement in symptoms, was noticed. The tremor, in fact, seemed somewhat aggravated. The amount of benadryl was then reduced to the original daily dose of 200 mg and scopolamine three times daily was added to this therapy. It was noted that the patient had less tremor and felt less nervous when the scopolamine was given in addition to benadryl.

On May 9, 1947, an attempt was made to substitute pyribenzamine for benadryl, but after 4 days the patient begged for resumption of the benadryl. He remarked at that

time that he was sweating profusely and constantly and that locomotion was becoming poor. Upon a return to benadryl relief was noted within 3 days. This patient had been on 50 mg of benadryl four times daily and 0.6 mg of scopolamine three times daily for over 1 year when he was last seen. The initial improvement, noted shortly after the institution of benadryl therapy, had been maintained. There was no evidence that tolerance to the drug was developing. On the other hand, there was no evidence that the drug was producing any gradual or steady improvement in symptoms. Evidently, the original response, which had developed within the first few weeks, was not further improved by continued use of the drug or by raising of its dosage.

**CASE 2** H S, a 68-year-old man, had had typical Parkinson's disease for 4 years. The coarse tremor and hypertonicity of muscles were incapacitating. He was unable to dress or feed himself, and he had to be helped out of a chair when he tried to stand up. He walked with a typical shuffling gait, and the body was stiffly bent forward from the hips and shoulders. He was frequently awakened during the night by cramps in the muscles, which his wife had massaged for relief. Medication had consisted of eight "rabellon" tablets daily. There was no past history of encephalitis.

The patient was started on 50 mg of benadryl four times daily. Within 7 days he was able to stand up from a sitting position unaided. He was also able to dress himself and to handle a knife and fork, although with difficulty. It was noted that he often sat for 1 hour without tremor, and he was able to walk with longer steps and without shuffling. Within 2 weeks he was able to sit quietly in church for the first time in 3 years, and he even found it possible to sit quietly through a 3-hour symphony concert. The nocturnal muscle cramps disappeared, and he was able to sleep through the night without interruption. He gradually reduced the "rabellon" dosage to three tablets daily and he later remarked that he often did not take any for a day at a time. When this patient was last observed 3 months after starting benadryl therapy, he was leading a normal business and social existence without any apparent handicap from the occasional coarse tremor that at times became manifest.

**CASE 3** M F, a 66-year-old housewife, had been suffering from Parkinson's disease for over 5 years. The symptoms started mildly but gradually progressed. After 4 years she became nearly helpless and was hospitalized for 6 months. The only medication consisted of 0.15 gm of stramonium three times daily. She had complained of a "neuritis" in the right arm for 5 years, and during that period she had kept the arm close to the side of the body, using only the portion distal to the elbow joint. She complained of cramps in the knees, which kept her awake at night. There was no past history of encephalitis.

This woman demonstrated typical Parkinsonian tremor of fingers, chin and mouth. The face was mask-like. The walk was stiff, and the feet shuffled. The right arm was painful and was held stiffly against the side of the chest. Any attempt by the examiner to abduct the right arm or to extend the elbow was vigorously opposed by the hypertonic and rigid muscles. Forced motion of this arm caused severe pain. The patient was started on 50 mg of benadryl four times daily but was advised not to discontinue the stramonium. After 3 days of medication she gleefully greeted the physician, when he entered her room, by extending the right arm to shake hands. She remarked that she had been unable to do this for over 2 years. During the next 3 weeks she began to eat with a fork instead of using the fingers, to drink water from a glass instead of using a drinking tube, to fold a napkin, to make her own bed, to cut with scissors and to write a letter fairly rapidly and legibly. One of the first symptoms to disappear was a profuse and uncomfortable perspiration. The pain in the right arm disappeared entirely. An attempt was made to withdraw the stramonium, but the

\*Clinical assistant in medicine, Albany Medical College Albany, New York attending physician and associate cardiologist House of Mercy and St. Luke's hospitals

tremor seemed to increase without it. As noted in other cases, complete withdrawal of the parasympathetic inhibitory drugs caused some aggravation of symptoms.

**CASE 4.** S. B. A. 68-year-old man, had suffered from Parkinson's disease for 10 years. He had tried many types of therapy including pyridoxine administered orally and by injection. He had been taking four "rabbellon" tablets daily for 3 years before starting on 50 mg of benadryl four times daily. The patient had been unable to feed himself for the preceding 3 years and he had been unable to dress himself for the previous 8 months. He had the usual difficulty in walking and the feet scuffed the floor. He complained of a very annoying sialorrhea and dysphagia. He noticed improvement within 1 week after starting the benadryl therapy. The improvement continued and when he was last seen about 2 months after institution of therapy, the transformation was remarkable. He stated that he could dress and feed himself write his name legibly and even lie down or get up out of bed without help. Formerly he could not even sit down or stand up from a chair without assistance. He remarked that he could walk much farther without fatigue, and that the feet no longer scuffed the floor or the sidewalk. The sialorrhea and dysphagia disappeared. He noticed that he was less uncomfortable in hot weather after taking benadryl. He stated that at night he had formerly slept about 1 hour at a time before being awakened by a cramp in an extremity or by inability to turn in bed to a more comfortable position. He had obtained relief with sodium amylal, which he took frequently at bedtime. He found that benadryl enabled him to sleep all night, and he was able to dispense with the use of sedatives entirely. However, he was never advised to discontinue the rabbellon since, in the other cases it had been found that the parasympathetic-inhibitory drugs and the benadryl seemed to have a definite synergistic action.

**CASE 5.\*** A. B. A 65-year-old single woman, developed weakness and easy fatigability about 3 years before she was first examined. It was gradually noticed that tremor of the hands and fingers particularly on the left side, had developed. The weight dropped from 124 to 98 pounds and thyrotoxicosis was suspected. The basal metabolic rate was +37 per cent, falling to +24 per cent after 2 months of thiouracil therapy but without any clinical improvement. The patient was noted to have a mask-like face, coarse tremor of the hands and fingers and shuffling gait, and the trunk and spine were bent stiffly forward. On scopolamine therapy (0.4 mg twice daily) she showed considerable improvement even to the extent that the basal metabolic rate fell to +14 per cent. She was maintained on this therapy for 4 months and was then shifted to 50 mg of benadryl three times daily. She immediately noticed further improvement. There was much less fatigue, and she slept better and worried less. She found herself able to move about with a great deal more ease, but she had a temporary setback when she fell downstairs the accident probably being the result of overconfidence in her abilities. She showed no added improvement when the benadryl dosage was raised to 300 mg daily. The final dosage was maintained at 200 mg daily divided into four doses.

**CASE 6.** A. G. F. A 66-year-old housewife, had been suffering from typical Parkinson's disease for 2 years with slight relief from atropine. She was started on 50 mg of benadryl four times daily. When she was seen 1 month later there was a great deal of improvement in the tremor, and walking was better. She remarked proudly that she was able to write letters quickly and quite easily, whereas formerly a single letter took days to complete. She was later tried for several days on pyribenzamine in equal dosage, but there was an immediate aggravation of symptoms, which were at once relieved when she returned to Benadryl.

**CASE 7.** S. G. A 68-year-old woman was seen after a 2 year history of progressively increasing symptoms of Parkinson's disease. She was given 100 mg of benadryl three times daily with considerable improvement during the first few weeks but without much noticeable benefit thereafter.

**CASE 8.** O. N. A. A 72-year-old man was never seen by me or by my associates. He was suffering from Parkinson's disease and was advised by the patient in Case 2 to take

benadryl for his symptoms. The patient's wife stated that she and her husband were satisfied with the results. "If benadryl doesn't do any more than to continue to make our nights more restful, it will be wonderful we need to be up and down all night long just in a nervous dither but now after using it just 28 days he sleeps through the night. The neighbors remarked a noticeable change in the way the patient walked and turned around much more easily. He could also get up and out of chairs more easily."

The patient who had had this condition for about 11 years had previously received atropium which he had not taken since starting benadryl therapy.

## DISCUSSION

The obvious benefits derived from the use of benadryl in the cases reported above can hardly be considered due to the enthusiasm with which a new drug is often administered. The victims of Parkinson's disease are not readily subject to suggestion since they have all suffered from their illness too long to welcome a new therapy with much faith. However, the good results obtained in this small group may not withstand the test of larger series of cases.

The beneficial results are not readily explained. An atropine-like action of the drug has been described,<sup>2</sup> and its effect in Parkinson's disease may be similar to that of atropine. Furthermore, con- gestion of the choroid plexus has been observed in animals intoxicated with benadryl.<sup>1</sup> This effect may produce an enhancement of the circulation of the corpus striatum, where the symptoms of paralytic agitans are initiated.

## SUMMARY

Eight patients suffering from paralysis agitans, (Parkinson's disease), all of them in the arterio-sclerotic group, were treated with benadryl over a period varying from three to fourteen months. All patients noted considerable improvement in the symptoms so long as the drug was administered.

Four of the treated patients continued to use parasympathetic-inhibitory drugs of the atropine series, and there seemed to be a synergistic action between these drugs and benadryl. A closely related antihistamine drug, pyribenzamine, apparently was ineffective in the treatment of Parkinson's disease.

The possible mechanism of action of benadryl in this disease is briefly discussed. Its use is suggested as an added therapeutic weapon to be administered alone or in conjunction with the atropine-like drugs.

Since this paper was submitted for publication 2 additional cases of Parkinson's disease have been treated with benadryl. The response to the drug was excellent in both cases.

## MEDICAL PROGRESS

### INTERCAPILLARY GLOMERULOSCLEROSIS

PAUL KIMMELSTIEL, M.D.,\* AND WILLIAM B. PORTER, M.D.†

CHARLOTTE, NORTH CAROLINA, AND RICHMOND, VIRGINIA

IN 1936 a small series of cases was reported by Kimmelstiel and Wilson<sup>1</sup> showing a conspicuous correlation between a syndrome of diabetes, nephrotic edema, gross albuminuria and hypertension and a peculiar type of intercapillary sclerosis of glomeruli. The nature of this investigation, taking its origin from systematic analysis of a large volume of autopsy material, precluded a specific detailed study of clinical features. The relatively scant clinical information was merely sufficient to emphasize the significance of the histologic findings. A large number of similar cases have been reported during the last twelve years, and with them a wealth of clinical experience has supplemented the sketchy notes that accompanied the original description.

Although, by and large, most authors confirmed these observations, an analysis of the literature has brought to light conflicting reports and divergent interpretations. The term "intercapillary glomerulosclerosis" has been maintained in most publications, a consoling circumstance for those who review the literature, but the name hardly veils the violent disagreement concerning the true nature of the condition. Many problems have been raised that still await clarification. The specificity of the glomerular lesion, the incidence of its occurrence, its relation to diabetes, the accurate definition of the clinical syndrome, the histogenesis and many other questions are still under discussion.

A survey of the literature has convinced us that many of the discrepancies originate from differences in the interpretation of histologic findings. It appears to us that this explains why some authors believe the lesion to be highly specific, whereas others use it to illustrate the general concept of nonspecificity of glomerular lesions.<sup>2</sup> It is also the obvious reason for wide variation in incidence reported by various authors, ranging from 15.0 to 63.7 per cent in autopsy material on diabetic patients. An attempt to clarify the histologic criteria must therefore precede consideration of the remaining problems.

#### SPECIFICITY OF GLOMERULAR LESIONS

All observers have readily recognized the striking and characteristic change of the glomeruli. If fully developed, it consists of a hyaline mass in the central portion of the glomerular lobules, creating the impression of being situated between the capillaries. Different authors, however, vary considerably in

their opinion concerning the specificity of this lesion for diabetes. Occurrence of intercapillary glomerulosclerosis in nondiabetic, arteriosclerotic kidneys has been reported as varying from 0.8 to 12.0 per cent,<sup>3,4</sup> and as high as 25.4 per cent (Horn and Smetana<sup>5</sup>). Siegal and Allen,<sup>6</sup> on the other hand, found typical changes in only 1 out of 100 nondiabetic, hypertensive patients, and Bell<sup>7</sup> states that he considers intercapillary glomerulosclerosis (of the nodular type) almost pathognomonic for diabetes. The relatively frequent occurrence of intercapillary glomerulosclerosis in cases of glomerulonephritis is discussed separately below.

All authors who observed intercapillary glomerulosclerosis in a significant number of cases in the absence of diabetes emphasize that the involvement was of "minimal severity" or of a mild degree. It seems, therefore, that previous statistics should be re-evaluated in the light of the criteria used for the recognition of the lesion.

No claim of specificity was made in the original report,<sup>1</sup> and the change in the glomeruli was described as representing merely an extreme degree of a process, milder forms of which are frequently found in nondiabetic kidneys of aged persons. Allen,<sup>8</sup> however, concluded from his detailed studies that the lesion under consideration is highly specific and differs not only quantitatively but also qualitatively from similar degenerative glomerular changes. His concept has been accepted in part by many writers. He showed that the hyaline mass contains markedly argentophilic laminated fibrils differing conspicuously in intensity of impregnation and arrangement from those seen in hyalin associated with nondiabetic glomerulosclerosis. Also noted was a relatively increased resistance to tryptic digestion of the "diabetic" hyalin in contrast to the nondiabetic hyalin. It is apparent that these criteria reinforce the contrast between diabetic and nondiabetic hyalinization, but in our opinion they do not establish a clear-cut line of cleavage between specific and nonspecific changes.

Bell<sup>7</sup> has attempted to clarify the situation by subdividing the glomerular changes into the nodular and the diffuse type.

#### Nodular Type

This change, consisting in sharply defined spherical bodies, is apparently the same as that originally designated as "severe degree."<sup>1</sup> The renal involvement can be graded according to the number of

\*Pathologist Charlotte Memorial Hospital, Charlotte, North Carolina.

†Professor of medicine, Medical College of Virginia, Richmond, Virginia.

nodules per glomerulus and the number of glomeruli presenting the lesion

There can be no doubt that the nodular type is occasionally observed in cases in which diabetes can reasonably safely be excluded. Siegal and Allen<sup>8</sup> have presented convincing evidence in a patient who demonstrated all other components of the syndrome but whose fasting blood sugar level was within normal limits. Unfortunately, a glucose-tolerance curve was not determined. The overwhelming majority of such cases, however, are found in kidneys of diabetic patients. This lesion, according to Fahr,<sup>9</sup> "is seen infinitesimally more rarely in nephrosclerosis without diabetes," and Bell<sup>7</sup> considers this type almost pathognomonic for diabetes. With few exceptions most writers have concluded that the nodular (severe) type constitutes a reliable aid to the diagnosis of diabetes at autopsy. Even the authors who reported a relatively high percentage of intercapillary glomerulosclerosis in cases without diabetes observed that diabetes is rarely absent if the glomerular lesions are severe.<sup>1, 3-6, 10-12</sup> Dr. A. C. Allen, in a personal communication, goes so far as to say

In view of our experiences and those of our associates over the past years I am altogether convinced of the specificity of the nodular lesion which is the only lesion that is of current pertinence. I should strongly suspect that the finding of a nodular lesion in a non-diabetic means either that the mild form of diabetes mellitus, which these patients often have, has been overlooked, or that there has been a confusion of the definitive histologic criteria that this lesion possesses.

### Diffuse Type

Bell<sup>7</sup> does not give a detailed description of this lesion except for stating that it resembles the changes in chronic glomerulonephritis and is formed by splitting of the inner basement membrane. This type, according to Bell, may be present alone or in conjunction with the nodular type. Although it is not certain, it is most likely that the diffuse form is identical with what other authors have designated as "less severe degrees." This form is apparently more frequent in cases of diabetes than the nodular type, but at the same time is more common in non-diabetic patients.<sup>3, 4</sup> According to Bell<sup>7</sup> the nodular lesion occurred in 15.9 per cent of cases of diabetes, and the combined nodular and diffuse form in 29.2 per cent — that is, almost twice as often. It is inferred from Bell's description that the diffuse lesion is not always readily identified and correctly interpreted. Hence, no accurate estimate can be made of its specificity. The diffuse or less severe type of intercapillary glomerulosclerosis does not possess sufficient histologic characteristics to be distinguished from other intercapillary glomerular changes, and its relation to diabetes is yet to be explored. It is conceived by most authors as a forerunner of the nodular type. In its mildest form<sup>13, 14</sup> Wilson<sup>1</sup> linked it to a rather frequent glu-

change in senile kidneys, which they believed to be only indirectly connected with vascular sclerosis and which they were not able to correlate with diabetes. They termed this process "axial" glomerular thickening — an "aging" process. It is of interest to compare this interpretation of histologic findings with Goodof's<sup>2</sup> statement that the glucose-tolerance curve in older patients often approaches that of diabetes, apparently parallel to the aging process of the glomeruli.

The final proof of the specificity of intercapillary glomerulosclerosis, namely, the experimental reproduction of the lesion has been attempted by Lukens and Dohan.<sup>15</sup> These authors rendered a dog diabetic

TABLE 1 Frequency of Intercapillary Glomerulosclerosis Reported in the Literature

with extract of the anterior lobe of the pituitary gland. The dog maintained diabetes during a five-year period. A post mortem examination revealed lesions in the kidneys resembling early lesions of intercapillary glomerulosclerosis.

In summary, an evaluation of available statistical data reveals that the nodular or severe type of intercapillary glomerulosclerosis can be regarded as almost specific for diabetes. If, however, the diffuse, or less severe type, is included in the statistics, the incidence of its occurrence in diabetes rises as its specificity falls. A clear distinction between the two types is therefore imperative if the concept of a specific "diabetic" glomerulosclerosis is to be saved.

### FREQUENCY

The survey of the literature does not permit final conclusions concerning the frequency of intercapillary glomerulosclerosis since it is not always possible to determine how strictly the histologic criteria have been applied. Even if confined to reports in which one can be reasonably certain that the nodular type is referred to, the figures vary greatly (Table 1). From a selection of such statistics, which lend themselves to reasonably secure interpretations, the conclusion is drawn that intercapillary glomerulosclerosis occurs in approximately 17 per cent of all cases of diabetes, about twice as often in women as in men.

It apparently occurs —

decades of life (Fig 1), only 3 cases being reported at the ages of sixteen,<sup>4</sup> seventeen,<sup>3</sup> and nineteen,<sup>3</sup> although the lesions were only of a mild or diffuse type in at least 1 of these cases (the degree was not

FIGURE 1 Occurrence of Intercapillary Glomerulosclerosis according to Decade of Life

clearly indicated in either of the other cases) After that a slow rise occurs in the third decade of life, although, again, these cases seem to be of milder degree.<sup>3</sup> The incidence subsequently rises further, to

in chronic glomerulonephritis.<sup>4, 16</sup> How often this occurs is difficult to estimate since most authors do not indicate the degree or type observed. In most cases it is relatively simple to segregate the diffuse type of intercapillary glomerulosclerosis in chronic glomerulonephritis from that in diabetes. The main distinguishing features have already been discussed by Kimmelstiel and Wilson<sup>1</sup> and later by others. Since intercapillary glomerulosclerosis begins in the center of the lobule and glomerulonephritis in the peripheral capillaries, the former usually shows widened peripheral capillaries with a clearly demarcated basement membrane, and the latter shows narrowed capillary lumens with a blurred basement membrane. Additional general criteria, as a rule, make the differentiation relatively simple.

Cases of chronic glomerulonephritis, however, are seen in which the kidneys show occasional, or even numerous, glomeruli indistinguishable from the nodular type of intercapillary glomerulosclerosis, and in these cases diabetes is known to be absent. Are the morphologic changes in these cases fundamentally the same or do they represent a different pathologic process? To our knowledge only one attempt has been made to answer this specific question. Henderson et al.<sup>16</sup> made a comparative clinical

TABLE 2 Points of Difference between Patients with Chronic Glomerulonephritis Associated with Intercapillary Glomerulosclerosis and Patients with Diabetes and Intercapillary Glomerulosclerosis

CONDITION	AVERAGE AGE OF PATIENTS	EDEMA	ALBUMINURIA	SPECIFIC GRAVITY	UREA NITROGEN	ANEMIA	RETINOPATHY	DURATION OF TERMINAL ILLNESS	CAUSE OF DEATH
Diabetes with intercapillary glomerulosclerosis	58	Less prominent	Less intense	Higher	Lower	Less severe	Diabetic type	Months to years	Varied
Glomerulonephritis with intercapillary glomerulosclerosis	32	More prominent	More intense	Lower	Higher	More severe	Hypertensive type	1 to 4 months	Usually cardiac, renal or infections

reach its maximum during the sixth decade, thereafter declining slightly. Bell's statistics seem to represent best the general impression gained from a survey of the literature.

In summary, intercapillary glomerulosclerosis of the nodular type occurs in approximately 17 per cent of all cases of diabetes, most frequently during the sixth decade of life.

#### RELATION TO CHRONIC GLOMERULONEPHRITIS

Clinically, these conditions may closely resemble each other. Diabetic patients with albuminuria, nephrotic edema, hypertension and renal insufficiency have often been diagnosed as having diabetes complicated by independent glomerulonephritis.<sup>6, 16</sup> Derow et al.<sup>19</sup> pointed out that aside from the age, the absence of previous history of acute glomerulonephritis may be the only information of differential significance.

There is no doubt that intercapillary glomerulosclerosis may occur in a significant number of cases

study that revealed the following facts: cases of chronic glomerulonephritis with or without intercapillary glomerulosclerosis show no significant clinical differences, and patients with chronic glomerulonephritis with intercapillary glomerulosclerosis differ from diabetic patients with intercapillary glomerulosclerosis in spite of superficial resemblances. Both groups have in common hypertension of varying degrees, albuminuria, edema and retinopathy. The points of difference are summarized in Table 2. This analysis clearly depicts the essential clinical differences between glomerulosclerosis and chronic glomerulonephritis in general. The authors conclude from this comparison that intercapillary glomerulosclerosis in diabetes constitutes a pathologic process different from intercapillary glomerulosclerosis accompanying chronic glomerulonephritis, although they closely resemble each other histologically. It should be taken into consideration, however, that most of the clinical differences are quantitative ones. It appears questionable that the pro-

found changes in protein metabolism and in renal function that occur in chronic glomerulonephritis could be altered perceptibly by the accompanying intercapillary glomerulosclerosis, which, by itself is associated with similar changes of a lesser degree. If intercapillary glomerulosclerosis of the diabetic type occurs in chronic glomerulonephritis, it may be expected that the related clinical symptomatology is completely masked by that of the glomerulonephritis. Only the retinopathy is different in quality in the two conditions, and, as pointed out below, this type of retinopathy is directly dependent upon the diabetes rather than upon the renal lesion.

We are therefore inclined to assume that the same process of intercapillary glomerulosclerosis that occurs in diabetes also occurs in chronic glomerulonephritis. The fact that it is relatively more common in glomerulonephritis than in any other disease except diabetes should prompt one to search for a metabolic disturbance prevalent in both conditions as the precipitating factor.

In summary, the clinical symptomatology of intercapillary glomerulosclerosis in diabetes and of chronic glomerulonephritis may resemble each other closely. Signs of importance in the differential diagnosis are briefly tabulated. Histologically, the lesion may be indistinguishable at times, although in the majority of cases, the differences are obvious. There is no reason to assume a difference in pathogenesis between diabetic intercapillary glomerulosclerosis and intercapillary glomerulosclerosis in chronic glomerulonephritis.

#### RELATION TO NEPHROTIC SYNDROME

If the nephrotic syndrome is defined as a condition characterized by albuminuria, hypoproteinemia, hypercholesterolemia and edema, it may be stated that this has not been reported in cases of diabetes without intercapillary glomerulosclerosis.<sup>4</sup> On the other hand, fully developed nephrosis does not often participate in the complex syndrome connected with intercapillary glomerulosclerosis. Albuminuria is present in most cases and seems to be roughly parallel to the severity of glomerular involvement,<sup>8</sup> but lesser degrees of albuminuria may be related to cardiac or other renal lesions. Exact figures in that respect are not available, but most authors agree that significant albuminuria (a +++ test) occurs in the majority of cases. However, Bell<sup>17</sup> reports that no albumin or a faint trace was found in 29 per cent of his cases of intercapillary glomerulosclerosis. Here, again, mild or diffuse lesions may have been included in this series.

Available data concerning hypoproteinemia, hypercholesterolemia and edema are rather incomplete and vary considerably. Some of the earlier reports with relatively small series show rather high percentages. Newburger and Peters<sup>20</sup> and Porter and Walker<sup>21</sup> report the presence of significant albuminuria, hypoproteinemia and edema in 75 to 100 per

cent of cases. Hernandez Morales<sup>18</sup> reports a nephrotic picture in all of his 6 cases. Siegal and Allen<sup>8</sup> likewise stress the common occurrence of the nephrotic syndrome. In later large series, however, its occurrence is reported to be considerably less frequent. Goodfo<sup>3</sup> observed edema on a hypoproteinemic basis in 30 per cent of 18 cases with advanced lesions. Laipply<sup>4</sup> found that the nephrotic syndrome was present in only 6.3 per cent. Bell<sup>17</sup> states that only about a third of his cases showed edema and that in no case was it so marked as that in lipid nephrosis, 7.5 per cent. Grade 2 to 3 edema occurred in his cases of nodular intercapillary glomerulosclerosis. Henderson et al.<sup>16</sup> state that some degree of edema was present in 47 per cent of their cases of intercapillary glomerulosclerosis, but in only 6.6 per cent could the edema be classified as nephrotic in type. It seems justifiable to assume that with application of more rigid criteria, edema of the nephrotic type seems to occur in less than 10 per cent of cases of intercapillary glomerulosclerosis.

In summary, a significant degree of albuminuria occurs in the majority of cases of intercapillary glomerulosclerosis. The nephrotic syndrome, however, seems to occur in less than 10 per cent of the cases of intercapillary glomerulosclerosis verified by autopsy. It is of significance that no cases have been recorded of diabetes with nephrosis in which intercapillary glomerulosclerosis was not demonstrated.

EDITH E. PARRIS, *Assistant Editor*

### CASE 34251

#### PRESENTATION OF CASE

A sixty-three-year-old businessman entered the hospital because of persistent epigastric pain of eight months' duration.

Fifteen years and again five years before admission the patient had epigastric distress, which occurred following meals and also at night, awakening him from sleep. In both episodes the symptoms were relieved by food, milk and sodium bicarbonate. Eight months before admission he experienced similar but more severe epigastric distress and pain and did not respond to the usual regime. There was increasing anorexia, fatigue, lassitude and a weight loss of 20 pounds. The patient complained of generalized pruritus of two months' duration. He had had no jaundice or change in character of stools or urine. Unusual business and family problems existed during the period before he entered the hospital. An x-ray film of the gastrointestinal tract two weeks before admission showed the lower esophagus to be slightly wider than usual, and its folds were more prominent than usual, though not definitely tortuous. The proximal part of the stomach revealed no evidence of a filling defect, and peristalsis was normal. The pylorus and prepyloric region were spastic and narrowed throughout most of the examination but filled to a wide diameter at times and appeared distensible throughout. There was a suggestion of a small, constant accumulation of barium on the lesser curvature and antrum, which might have represented a small crater, mucosa appeared to be present in this region. The duodenal cap and loop were not remarkable. After six hours most of the barium lay in the terminal ileum and right colon, but there was a small residuum of barium mixture with fluid in the stomach. A qualitative test for sugar with Benedict's reagent was olive green. There was no bile or albumin in the urine. The red-cell count was 5,430,000 and the white-cell count 7600. After two weeks on a strict regimen for peptic ulcer the patient's symptoms were unrelieved. It was believed that he should be hospitalized in view of the x-ray findings to determine more clearly the nature of the lesion and to regulate his diabetes at the same time.

Physical examination showed a well nourished man with slight icterus of the scleras. A moderately firm, nontender lymph node 1 cm. in diameter was felt in the left axilla. The heart and lungs were negative.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 70 diastolic.

Examination of the blood disclosed a hemoglobin of 14.4 gm. and a white-cell count of 12,900, with 76 per cent neutrophils. The urine had a specific gravity of 1.032 and gave a + test for albumin and a ++ test for bile, and the test for sugar was green. The sediment contained occasional pus cells. The fasting blood sugar was 171 mg., the phosphorus 3.0 mg. and the alkaline phosphatase 24 units per 100 cc. The serum bilirubin was 3.2 mg. per 100 cc. direct, and 4.0 mg. indirect. The fasting blood sugar on the second hospital day was 250 mg. per 100 cc. A gastric analysis revealed no free hydrochloric acid in the first specimen, but the third specimen contained 40 units of free acid, and the total acid was 51 units. The prothrombin time was 20 seconds (control, 21 seconds). The cephalin-flocculation test was negative. A stool was mustard colored.

An x-ray film showed the esophagus to be as before. The stomach was dilated and contained considerable fluid so that adequate examination was impossible. There was an area of irregularity in the prepyloric and antral regions. On the lesser curvature over a considerable distance, about 6 cm., was what appeared to be shortening of this portion of the stomach. It was not certain that there was a filling defect in this region. The second portion of the duodenum was narrowed, and there appeared to be pressure on its medial aspect. At the end of six hours most of the barium remained in the stomach, which was dilated.

Following admission to the hospital the patient became frankly jaundiced. He continued to have a great deal of epigastric pain, nausea without vomiting, and diarrhea. The pain was only partially relieved by milk and gelusil.

An operation was performed on the thirteenth hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: This is going to be the shortest discussion on record, I hope.

"Unusual business and family problems existed." I looked at that statement with a good deal of skepticism because it appears to be trying to tell me that this man had an ulcer.

This patient had partial biliary obstruction. He had had it for some time. The fact that he itched, the fact that he had a measurable as well as an observable amount of icterus and that the alkaline phosphatase was considerably elevated means partial biliary obstruction. The common causes are

operative trauma (this patient had had no operation), stone in the common duct and tumor, especially tumor of the biliary tract or head of the pancreas. One other bit of evidence—this man had mild diabetes. It is my opinion that mild diabetes is commonly associated with chronic gall-bladder disease.

The question is, How are we going to decide whether this was tumor or stone? I am going to say that the patient had a stone in the common duct.

I must say one or two more things. Once in a blue moon one finds a peptic ulcer that will cause biliary obstruction. The ulcerative lesion is in the mid-portion of the duodenum, and in the cases that I have seen, the ulcers have been large. I do not want to insult the X-ray Department by telling them that this man had a large ulcer in the duodenum. It is stated that the duodenum was narrowed. Carcinoma of the pancreas is sometimes associated with widening of the duodenal loop. That is not mentioned here, but there was a suggestion of pressure on the medial side of the duodenum. From the report, that is the impression I got, which *should* lead one to the diagnosis of tumor.

There are various other exotic conditions such as xanthoma with obstruction of the biliary tract. Another rare situation is that of lymph-node involvement by tumor, with pressure on the bile duct and partial biliary obstruction. That is relatively rare, but I have to consider this lymph node in the axilla and I wondered if that might be part of a metastatic process. I cannot conceivably rule out a malignant process, and I have to put Dr. Wyman on the spot in just a moment because I am discounting some of these x-ray findings. For instance, stasis was marked on x-ray examination, but nothing is said in the record about clinical signs of stasis. There was no vomiting and no statement regarding intubation of the stomach, and it seems from the history that no one was impressed by this x-ray evidence of stasis. I get the impression that the x-ray findings were due to a change in motility. One can have changes in motility from biliary obstruction alone. The problem then is, Did this patient have carcinoma of the stomach with extension to give partial biliary obstruction? I will say before I see the x-ray films that I do not believe that he had carcinomas. The operation was a laparotomy, the stone was removed, and he was probably cured. May we see the x-ray films?

DR STANLEY M. WYMAN: The irregularity of the prepyloric and the antral regions is best seen in these two large films. The spot films did not show the lesion as we hoped they might. The area in question was flexible and distensible. The mucosa seemed to run throughout it. The duodenal cap filled out to a good normal contour and seemed to show no deformity or evidence of crater. The narrowing of the duodenum that is mentioned seems to be in the

second portion and seems to be somewhat changing in character. There is a suggestion of the so-called "inverted three" sign, which is often present in tumor. This was not definite. We concluded that the patient had pressure on the medial aspect of the second portion of the duodenum and that he had disease in the prepylorus, which was perhaps old and represented scarring. There seemed to be no evidence of infiltration of the second portion of the duodenum, and this was considered a purely extrinsic pressure manifestation.

DR RICHARDSON: That was fairly definite though?

DR WYMAN: Yes, it seemed definite.

DR RICHARDSON: It shows what seems to be pressure.

DR WYMAN: It is not widened, though. The loop does not seem increased in size on that film. On this film it is larger than usual, and the second portion of the duodenum seems to lie more toward the right than one would expect. This is a six-hour film at the second examination, showing considerable retention of barium in the stomach.

DR RICHARDSON: I cannot laugh off this lesion in the prepyloric region. It must be an intrinsic lesion.

DR WYMAN: I believe so. My own impression was that it was a scar due to a previous ulcer.

DR RICHARDSON: I have to take that lesion in the stomach seriously, and it may well account for the stasis. I am not sure how seriously to take the duodenal lesion. If one takes it really seriously, it is evidence in favor of tumor. I do not see how it could have been an ulcer of the midportion of the duodenum with biliary obstruction. I will say that the patient had, in addition to stone, a benign gastric ulcer, since he had a history of epigastric pain going over fourteen years or more—a long period.

I shall summarize, then, by saying that he had a stone in the common duct and benign gastric ulcer, perhaps healed at the moment, with a good deal of scarring, and I do not know what he had in the duodenum. What do you say, Dr. Adams?

DR F. DENNETTE ADAMS: I would put my money on tumor.

DR RICHARDSON: Where?

DR ADAMS: During the last fifteen minutes I fluctuated from pylorus to pancreas. In view of the fact that some relief from pain was afforded by a Sippy diet, I would put it in the pylorus.

DR WYMAN: What about stones?

DR ADAMS: I do not believe that the history is consistent with stones.

DR RICHARDSON: I thought perhaps on the law of chance that tumor would be more likely, but I will stick to stone in the common duct, and I believe that the operation was a laparotomy. It may have been a lymph-node biopsy from the right axilla,

which turned out to reveal a reticulum-cell sarcoma, or the operation may have been a gastroscopy. Do you still do that to us, Dr. Mallory?

DR. TRACY B. MALLORY: It was a laparotomy.

DR. ADAMS: One more statement—if this man had trouble from a stone in the common duct, he should have had some fever, I believe.

DR. RICHARDSON: He may have had. We had one extraordinary patient on the ward with itching of a year's duration and no fever who was operated on and a stone was found in the common duct.

DR. ADAMS: This man had so much jaundice and so much obstruction that he should have had fever.

DR. RICHARDSON: One had better say that the diabetes was incidental. Diabetes associated with carcinoma of the pancreas appears very late in the disease.

DR. ADAMS: That would be rare.

DR. RICHARDSON: Incidental diabetes goes better with disease of the gall bladder.

MR. GEORGE A. McLEMORE, JR.: How about diabetes with chronic pancreatitis?

DR. RICHARDSON: That would be in favor of stone.

DR. DANIEL S. ELLIS: This patient was first seen two weeks before admission to the hospital. The course at that time seemed perfectly typical of peptic ulcer, though the history of itching bothered me a little. When I found sugar in the urine I took it to be due to diabetes. The first x-ray film was reported as showing the presence of probable ulcer in the prepyloric region. In two weeks, between the time he was first seen and when he came back for x-ray and follow-up study, the patient had not had any relief on a strict ulcer regime, and he had continued to lose weight. He was admitted to the hospital because we thought he had a lesion in the stomach that probably should come out. We also hoped to find out more about the diabetic setup. He was not jaundiced, and he had no bile in the urine. As a matter of fact, the jaundice was not detected until two days after admission to the hospital, when he became frankly jaundiced, but he had bile in the urine. X-ray examination was repeated, and Dr. Wyman has described the findings. We also thought that he had involvement of the stomach, probably cancer of the stomach involving the pancreas or cancer of the head of the pancreas involving the stomach. As an outside possibility we hoped that this man had a chronic ulcer that had perforated into the head of the pancreas and caused a large inflammatory mass, which might have accounted for the pressure defect seen on the duodenum.

#### CLINICAL DIAGNOSIS

Carcinoma of head of pancreas?

DR. RICHARDSON'S DIAGNOSES

Stone in common bile duct

Gastric ulcer, ? healed

#### ANATOMICAL DIAGNOSIS

*Adenocarcinoma of common bile duct and papilla of Vater.*

#### PATHOLOGICAL DISCUSSION

DR. ELLIS: Dr. McKittrick explored the patient. The first surprise was that the stomach was entirely normal, perfectly free and fairly movable. There was no evidence of new or old ulcer that one could see or feel in the stomach or in the duodenal cap. We were a bit perplexed, and Dr. McKittrick explored the head of the pancreas, which felt perfectly normal. He tried to free up the duodenum, and in the second portion of the duodenum, before it was opened, there appeared to be a soft, movable mass, about the size of a man's thumb. The duodenum was then opened longitudinally, and for the moment it was difficult to visualize a mass. Subsequently, on the posterior wall, at the ampulla of Vater, an intramural mass was found, which seemed to involve the common duct. It was obviously a tumor involving the distal end of the common duct where it runs through the wall of the duodenum. The question was whether or not a radical resection and Whipple type of operation were to be done—or whether a local excision might be successful. Dr. McKittrick finally decided to attempt a local excision. He transected the duodenum and resected a segment about 5 cm in length, which included the papilla and portions of the common bile duct and the duct of Wirsung. He sewed the severed ends of the common duct and the pancreatic duct into the posterior wall of the duodenum and then made an end-to-end anastomosis.

DR. MALLORY: The specimen that we received was a segmental resection of the duodenum with the papilla of Vater in the center. The papilla was occupied by a tumor that proved to be a very well differentiated adenocarcinoma. A portion of the tumor was relatively benign in appearance, and another portion definitely invasive and malignant, suggesting that the tumor started as a benign polyp and later became malignant. Both polyps and carcinoma can occur in the ampulla of Vater.

DR. RICHARDSON: This does not sound as if it would account for the narrowing of the duodenum.

DR. ELLIS: It would have presented a defect in the lumen of the duodenum. There was no way that it would account for narrowing by compression from outside.

DR. ADAMS: How is the patient doing?

DR. ELLIS: The postoperative course was interesting. For three days it was excellent, but during the next twenty days he had a stormy time. A T-tube had been sutured into the common duct, and a cigarette drain in the foramen of Winslow. For the first few days the patient drained 700 cc of normal bile, then the wound began to drain copious quantities of bile-stained material, between

2200 and 2500 cc a day. With this much loss of fluids we were unable to keep the electrolyte or the nutritional balance. The chloride fell to around 83 milliequiv per liter, the nonprotein nitrogen rose steadily to 125 mg per 100 cc, and he became uremic and began to lose ground. Needless to say we became very worried about him. About a week postoperatively, we decided that we had to do a jejunostomy to feed him because anything we gave by mouth was coming out through the common duct. Almost as soon as jejunostomy was done, he improved, and whether it was time for him to get well or whether the procedure accounted for it we could not decide. We were able to feed him back the contents of the common-duct-tube drainage. The nonprotein nitrogen fell to normal within three or four days. The diabetes, which had been something of a problem immediately postoperatively, cleared up in time. At the end of about two months we sent him home. I talked to him yesterday and he has gained 5 pounds, is walking around and wants to go back to work.

A PHYSICIAN: Was the stomach opened?

DR ELLIS: No.

DR RICHARDSON: Therefore, a healed gastric ulcer has not completely been ruled out.

## CASE 34252

### PRESENTATION OF CASE

An eighty-one-year-old retired policeman was admitted to the hospital complaining of a mass in the neck and fever.

He had been in exceptionally good health all his life until six months before admission, when he noted a nontender area of swelling in the left side of the neck. The mass gradually increased in size and was noted by his family for the first time one month before admission. During the three weeks preceding admission it increased rapidly and he was aware of a shift in position of the hyoid bone as though his "windpipe were broken." Four days before admission he had a severe shaking chill followed by fever and marked weakness. There were no subsequent chills, but the fever continued until admission.

He had had mild dyspnea on exertion for several years and slight ankle edema but no orthopnea or hypertension.

Physical examination showed an obese man appearing much younger than his stated age. The fundi were normal. The posterior pharyngeal wall was slightly injected. No masses were visible inside the mouth. The neck was short and thick. A nontender mass, measuring 9 by 9 cm, occupied the left side of the neck, its upper and lower margins seemed to be bounded by fascial planes. Some observers believed it to be solid, others thought it was cystic. The trachea and the hyoid bone were

deviated to the right. The heart was questionably enlarged. The rate was grossly irregular at 110. No murmurs were heard. Scattered coarse rales were heard at the lung bases bilaterally. No organs or masses were palpable in the abdomen. The prostate was firm and enlarged to two and a half times the normal size.

The temperature was 102.2°F. The blood pressure was 110 systolic, 80 diastolic.

Examination of the blood demonstrated a hemoglobin of 14 gm and a white-cell count of 14,500, with 85 per cent neutrophils. The urine was not remarkable. The stools were guaiac negative. The nonprotein nitrogen was 41 mg and the total pro-

FIGURE 1

tein 62 gm per 100 cc. An electrocardiogram showed auricular fibrillation, with a ventricular rate of 95, and no other definite abnormality.

On x-ray examination the esophagus was found to be markedly displaced to the right and also somewhat anteriorly. There was no evidence of intrinsic involvement of the proximal esophagus. The mediastinum showed considerable widening, both superiorly and at the level of the hilar structures (Fig 1). X-ray examination of the nasopharynx and the base of the skull showed no abnormalities. The basal metabolic rate was -15 per cent.

During the first three hospital days the temperature gradually reached normal levels. On a low-salt diet and digitalis the respiratory symptoms subsided.

An operation on the neck tumor was performed.

## DIFFERENTIAL DIAGNOSIS

DR IRAD B HARDY May we see the x-ray films?

DR JAMES J McCORT These films show the mass described on the left side of the neck, displacing the trachea and the esophagus markedly to the right. A small amount of barium remains in the pyriform sinuses. The mediastinum is wide and continues so to about the level of the aortic arch. There seems to be a definite soft-tissue mass lying in this region. The heart is slightly prominent in the region of the left ventricle. The aorta is tortuous. A spot film taken of the barium in the esophagus shows the marked displacement described to the right and anteriorly.

DR HARDY Is there any calcification or any irregularity in the soft-tissue mass?

DR McCORT It seems to be smooth, and there is no calcification in it.

DR HARDY In summary, we have an eighty-one-year-old man who was essentially well until six months before he entered the hospital. At that time he noticed a gradually increasing mass in the left side of the neck, which was first noticed by the family one month before entry. It appeared to increase more rapidly in size over the three weeks immediately preceding entry, and a few days before he arrived in the hospital he had fever and a chill. Apparently he had no true obstructive symptoms from the mass. He had some cardiac symptoms that could be explained on the basis of the heart alone, I suppose, without obstruction.

So far as the physical examination is concerned, we find only a few points in the abstract that were abnormal. The mass in the neck is described as measuring 9 by 9 cm, it was nontender. Outside that there is nothing to help us. We would like to know whether it was freely movable or attached to the skin or more movable laterally than up and down—whether there was a bruit or any pulsatile qualities to the mass.

DR TRACY B MALLORY Dr Aub, can you answer any of those questions?

DR JOSEPH AUB The mass was rubbery, had a smooth edge and was enormous. It could be felt up and down the neck and deep into the mediastinum.

DR HARDY The patient was fibrillating. I assume, however, that that was incidental and was on the basis of arteriosclerotic heart disease. The prostate was two and a half times the normal size. He had had no genitourinary symptoms. I suppose he was entitled to that much enlargement at eighty-one years of age, it was probably benign hypertrophy.

Perhaps some of you could come out with a diagnosis now, but for me to try to make a working diagnosis it was necessary to go through the differential diagnosis of lumps in the neck. I still do not know whether I can make a diagnosis. We

might mention some of the possibilities purely to exclude them, I hope. In the first place, I thought of the so-called congenital lesions. A man of eighty-one is rather old for an initial appearance of these cystic structures, but there certainly are rare cases in which congenital cysts have appeared late in life, in middle age anyway. Branchial-cleft cysts occur and may occasionally degenerate into carcinoma. The cystic hygromas—the types of tumors that arise from lymph tissues—certainly appear most frequently in younger people, and I think they are usually lower in the neck, probably supraclavicular in most cases, the supraclavicular part being the largest part of the tumor. The thyroglossal cyst is midline, this was definitely lateral. I believe that the congenital types of lesion can be excluded, principally because of the patient's age.

We next should consider the infections—the involvement of the lymph tissue from infection, both acute and chronic, specific and nonspecific. I think that any acute lymphadenitis of this size would have been associated at an earlier date with more systemic symptoms of infection and that the lymph nodes would have been tender. It is definitely stated that this mass had never been tender. So far as the specific types of lymphadenopathy are concerned—for instance, tuberculosis—it would be most unusual for the first indication to appear at this age. Also, the size of the mass is very much against that particular type of pathologic process.

In passing, we must think of the so-called lateral aberrant thyroid tissue and possibly of cancer. The mass developed rather rapidly in size for such a lesion, however, and was probably much larger than one sees in that disease.

The fact that the patient was eighty-one and that in the transcript there was mention of widening of the mediastinum might make one wonder if this man had some type of aneurysm of one of the great vessels in the neck, such as the carotid. But there were no pulsations, the mass was not pulsatile. I think at that age an aneurysm would have had some calcification in its walls. Also, the widening of the mediastinum does not appear to have been aneurysmal in character. The aorta was somewhat dilated but probably consistent with his age.

That, to me, leads down to various tumors that can occur in this area. I should think that the growth was too rapid to consider the benign type of tumors that can occur in this area and reach good size. It could have been an enormous lipoma, but the soft-tissue shadow of lipoma is more or less pathognomonic. I believe that the systemic symptoms and the rapidity of the growth are against that diagnosis. The patient probably could have had a mixed tumor of one of the salivary glands, either the submaxillary or, less likely, the parotid. There again the rapidity of growth is

against a benign tumor. There are tumors of the carotid body, but if the mass in this case were such a tumor it would have been the largest one on record.

There are several things against the diagnosis of leukemia. Of course, the fairly well localized character of the lesion, the normal blood picture and, I suppose, the age are against that.

Metastatic carcinoma is certainly one of the more common conditions that we ought to consider in this age group. From the record it is my opinion that the growth, if the family first noticed it three weeks before entry, was too rapid for a metastatic carcinoma, and some studies were done to try to find a focus for the primary growth without success. The nasopharynx was normal, nothing was visible inside the mouth, and the stools gave a negative guaiac reaction — apparently the gastrointestinal tract was normal. The chest film, so far as the lungs were concerned, was also normal.

There are such weird tumors as the various types of sarcomas — fibrosarcoma, fibromyxosarcoma or something of that nature. I believe that the rapidity of growth and size are consistent with that type of lesion. I should think, without knowing the statistics exactly and having put a good deal of weight on the stated appearance of the mediastinum by the x-ray study, in which the hilar structures as well as the rest of the mediastinum superiorly were mentioned, that this represents probably a lymphosarcoma with some mediastinal-lymph-node involvement — the greatest amount of disease being in the location of the mass as described. The more I look at the film, however, the more I am impressed by the fact that this may have been some kind of huge tumor involving the left side of the thyroid gland, but I had not considered that too strongly beforehand and I think I will stick to the diagnosis of lymphosarcoma with some degeneration and softening in the late stages so that the question of whether or not it was cystic or solid was raised. Also, that would be enough to explain the rather recent fever and chills that this patient had.

Dr. McCORT: Did the mass move on swallowing?

Dr. AUB: As I remember, it did. It was a big tumor that pushed the trachea over so far that we thought the patient would suffocate. It extended downward from the jaw into the mediastinum. My recollection is that it moved with swallowing.

Dr. HARDY: That would favor some lesion of the thyroid gland.

Dr. McCORT: That is what I had in mind. In a short-necked person any deep tumor of the neck is apt to extend down to the superior mediastinum.

A PHYSICIAN: Was the tumor fixed to the skin?

Dr. AUB: No, it was not fixed.

Dr. MALLORY: Have you anything to add, Dr. Aub?

Dr. AUB: I am here because someone told me that I made a terrible error in this case. I do not believe that it was so serious after all. We arrived at the same conclusion as Dr. Hardy that some form of lymphoma was most probable, but we could not rule out a cyst and so thought it would be wise to stick in a needle. That is about what Dr. Hardy thought.

#### CLINICAL DIAGNOSIS

Malignant lymphoma?

Cyst of thyroid gland?

#### DR. HARDY'S DIAGNOSIS

Lymphosarcoma of cervical and mediastinal lymph nodes

#### ANATOMICAL DIAGNOSIS

*Colloid goiter, with cyst formation*

#### PATHOLOGICAL DISCUSSION

Dr. MALLORY: The mass was aspirated, and fluid very readily obtained. A minute biopsy was obtained at the same time, which showed a small amount of quite distorted granular tissue suggesting thyroid. Following that the patient was prepared for operation, and a large colloid goiter with extensive secondary cyst formation within it was successfully dissected.

Dr. ALFRED KRANES: What was the reason for the chills and fever? Was there any necrosis?

Dr. MALLORY: There was no very acute necrosis that we could see. He had had beta-hemolytic streptococci in his throat at one time.

Dr. KRANES: The febrile episode may have been independent.

Dr. McCORT: How do you explain the rapid growth?

Dr. MALLORY: Ordinarily, that is explained on the basis of hemorrhage and then secondary degeneration of the blood clot. However, the aspirated fluid was clear, not hemorrhagic, so that I have no good explanation. Growth must have been due to a rapid accumulation of fluid. There was nothing to indicate rapid growth in any of the solid tissue.

## TYPHUS FEVER IN BOSTON

ELSEWHERE in this issue of the *Journal* there is a report of 2 cases of typhus fever occurring in persons who have lived in Boston for many years. These cases should serve to call attention to the fact that typhus fever may be encountered in this vicinity from time to time. They also illustrate some interesting clinical and epidemiologic features of the disease and bring out some of the recent advances in the methods of more precise serologic diagnosis in the group of rickettsial infections.

Of particular interest is the fact that in both cases the clinical features, including the physical

and x-ray findings, were consistent with a diagnosis of the so-called primary atypical or "viral" pneumonia. Typhoid fever or some rickettsial infection was suspected only after the appearance of a rash. The fact that bacteriologic and serologic findings were negative for typhoid fever led to the serologic studies upon which the diagnosis of typhus fever was eventually established, first by the Weil-Felix reaction and finally by the tests for specific antibodies against the typhus rickettsias.

From an epidemiologic point of view the possible source of infection in these cases is of considerable importance. Both were isolated cases in which louse-borne infection seemed very unlikely. Nevertheless the results of the serologic tests indicated that the disease was indeed caused by the epidemic or louse-borne strain and not by the murine type of typhus rickettsia. It was then readily determined that both patients had immigrated many years ago from a part of Ireland where louse-borne typhus has been known to occur in epidemics from time to time in recent years. It was particularly significant that such epidemics had been recorded in the same area at the time when these patients were children and were still living there. These cases are thus brought within the group of infections usually known as Brill's disease.

These 2 cases should stimulate further discussion of Zinsser's hypothesis of the etiology of Brill's disease. Zinsser suggested that the mild typhus fever among immigrants from areas where classic typhus has occurred in the past represents a recrudescence of classic typhus many years after the initial attack. Serologic evidence supports this view, but proof must await the isolation and complete characterization of the strains of typhus from cases of Brill's disease. Such a study is currently in progress in the Rickettsial Disease Laboratory of the Harvard School of Public Health. It is hoped that clinicians who encounter suspected cases of Brill's disease will communicate with the Laboratory so that strain isolation may be undertaken, particularly in the first week of a patient's illness.

## WOTTON AND TRUETA ON SERVET

WILLIAM WOTTON was a child prodigy. By the age of five he could read the Bible in Latin, and when he was six no less a person than Sir Thomas Browne heard him read in English, Latin, Greek and Hebrew, "and construed the same truly." He entered Cambridge University at ten and graduated B.A. in 1679 at the age of thirteen. After a fellowship at St. John's College, Cambridge, he graduated M.A. when seventeen and was elected a fellow of the Royal Society in 1687, at the age of only twenty-one. In 1691 he was made a bachelor of divinity, and although he became a chaplain and later a rector, Wotton's chief contributions were literary. One book, published before he was thirty, made his name known to all historians, and medicine in particular is profoundly indebted to him for his *Reflections upon Ancient and Modern Learning*, first issued in 1694. It was in this book that Wotton called attention for the first time to Servet's description of the lesser or pulmonary circulation. The book itself, moreover, is remarkable, especially for a product of the seventeenth century, for it is chiefly devoted to the clear statement of facts. Wotton's *Reflections* is the best summary of the discoveries in nature and in physical science up to the time of its publication. A second edition was printed with additions in 1697, and a third in 1705.

The important notes on Michael Servetus, Spanish physician who was burnt at the stake on Calvin's orders in Geneva in 1553, were taken by Wotton from a copy of the passage in the *Christianismi Restitutio* furnished to him by Charles Bernard, a learned surgeon of London. Wotton never saw a copy of Servet's book. As we now know, only three of the one thousand printed copies, issued in 1553, are definitely known to have survived the fire. Servet, as pointed out by Wotton<sup>2</sup> in 1694, "clearly asserts, that the blood passes through the lungs, from the left to the right ventricle of the heart, and not through the partition which divides the two ventricles, as was at that time commonly believed." In addition, Servet anticipated Harvey in suggesting, but not confirming, the general circulation of the blood.

Thus Wotton, the scholarly divine, brought to the notice of the medical world the discovery of the pulmonary circulation.

Two hundred and fifty years have passed since Wotton's book was published. Much has been added to our knowledge of the Spanish physician and the life that he led in the passing years by biographers such as Allwoerden, Willis, Tollin, Gordon, Ward and Gener. The speeches for the prosecution and for the defense at the Geneva trial, among the most dramatic documents in the history of mankind have been published. More recently, Trueta,<sup>3</sup> a learned Catalonian surgeon, formerly in Barcelona but now at Oxford in England, has reviewed the life of Servet in a pleasant small book, *The Spirit of Catalonia*. He points out that Miquel Servet, to give him his Spanish name, born in 1511, even as a student in Barcelona showed a frankness and passionate love of free thought that got him into immediate trouble. He was shipped off to Toulouse and then to Italy, to Bologna and Padua, to Germany and elsewhere. He soon expressed heresies—on the nature of the Trinity and on the existence of the Son of God as a real man. After publication in 1531 of his first book, *De Trinitatis Erroribus*, he had escaped to France. Indeed much of his whole short life was one of fleeing from persecution. He managed to study anatomy in Paris, with Sylvius, Fernel and others, along with his fellow pupil, Vesalius Gunterius, the anatomist, praises both Vesal and Servet, who acted as his preceptors.

When danger came to Servet in Paris, because of his religious views and his outspoken manner, he went to Vienna, where he remained for twelve peaceful years as physician to a Cardinal. Here he arranged and edited an edition of the Bible, disclosing a wide knowledge on the most varied subjects of theology, history and natural science. It was in Vienna also that he wrote his greatest work, the *Christianismi Restitutio*. The manuscript, dated 1546, has also by chance been preserved and is now in the National Library of Paris.

In the light of present knowledge, how much credit should go to Servet for his clear insight into the great error? His book of 1553 hardly merits the construction, those of Valverde (1553) and

and Columbus (1559) both advancing the same theory of the circulation through the lungs, fared better Harvey knew of Columbus, but not of Servet, and to Harvey goes the honor of the greater discovery Servet's place in history, however, is secure, and is made more so by his fellow countryman, Trueta

### ADOPTION IN MASSACHUSETTS

A COMMUNICATION published elsewhere in this issue of the *Journal* calls attention to a problem with which most physicians are familiar the adoption of the illegitimate child The increase in illegitimate births in recent years seems to justify the conclusion that the problem will be present for many years to come, and in recognition of that fact, adoption laws in the Commonwealth have been under investigation by a commission that is expected to make recommendations for necessary revisions at this session of the Legislature

It is reassuring that a private organization such as the Boston Children's Friend Society continues to do its utmost to solve the problem of adoption Few decisions require more tact and skill than the suitable placing of a child unwanted under one roof, so badly wanted under another The ultimate welfare of the child is the primary consideration, but attention must also be given to the rights and feelings not only of the childless couple, who after having become attached to a child are sometimes forced to give him up, but also of the mother, who under the pressure of circumstances beyond her control may relinquish her child and later regret the step bitterly The Boston Children's Friend Society, through the efforts of specially trained workers, attempts to place these children in appropriate homes and also to make sure that the adoption will be permanent The child is given a complete examination, including physical, x-ray and psychologic study, and is placed in a boarding home for three or four

months before adoption Thus, there is sufficient opportunity for judging his physical and mental character, and the mother is given time to be certain that she wishes the child to be placed with a suitable family, the adopting parents are consequently spared the threat of litigation and possible removal of the child in the years when they have become most attached to him

The activities of the Boston Children's Friend Society merit the highest commendation every effort to ensure suitable and permanent homes for these children, and to enable them to grow up as self-respecting citizens of the community, should have the fullest co-operation and support of all elements of society

### MORTALITY OF INSURED INFANTS

INFANT mortality rates for the first year of life have been unusually low in recent years, according to a report made before the annual meeting of the Actuarial Society of America by Richard J Learson, vice-president of the Western and Southern Life Insurance Company of Cincinnati

Of particular interest is the observation that the death rate among insured infants has been only one third of the general infant death rate for the country as a whole Apparently we take especial care of that which we prize highly enough to insure Actuarial studies have shown further that infant mortality rates at all social and economic levels in the cities are lower than those in outlying regions

Pneumonia is listed as the leading cause of death, with congenital defects, debility and prematurity coming next, and diarrhea and enteritis third These three causes account for nearly 60 per cent of all the deaths under one year of age Obviously, much can still be done to preserve life at its beginning as well as to prolong it at its end

### MASSACHUSETTS MEDICAL SOCIETY DEATH

ST DENIS — J Nelson St Denis, M.D., of Roslindale, died on May 20 He was in his eighty-third year Dr St Denis received his degree from Baltimore University School of Medicine in 1892 His widow and five brothers survive

## MISCELLANY

### VETERANS ADMINISTRATION APPOINTMENT

Dr. William Reid Morrison, of Boston has been appointed chief consultant for surgery of the Veterans Administration. Dr. Morrison, a founder of the American Board of Surgery has been associate and clinical professor of surgery Boston University School of Medicine and surgeon in-chief of the first surgical service at Boston City Hospital.

## CORRESPONDENCE

### ADOPTION

To the Editor The adoption of the illegitimate child and the care of the unmarried mother are sometimes troublesome and baffling problems to the practicing doctor. It may be of interest to the physicians of this area to know that the Boston Children's Friend Society, which has been serving the children of the community for one hundred and fifteen years, has recently enlarged its adoption service. The child is placed for adoption by specially skilled workers who match the background and capacity of the infant and adopting parents and arrange suitable boarding care for the unmarried mother when needed.

Inquiries may be addressed to the general secretary Boston Children's Friend Society 123 Marlborough Street, Boston 16, Massachusetts.

HAZEL S. MORRISON, General Secretary

Boston Children's Friend Society

### CAUSE OF ELEVATED CEREBROSPINAL-FLUID SUGAR

To the Editor I am a loyal follower of your Journal and I believe I learn a lot from its contents. I wish to express my thanks, but also to point out an error appearing in my last number.

In the Case Records of the Massachusetts General Hospital (Case 34201) in the issue of May 13, Dr. Raymond D. Adams made the following statement "Elevated cerebrospinal fluid sugar is always [italics mine] related to a high blood sugar, either from diabetes mellitus or, as in this case, with no glycosuria from injection of glucose intravenously."

Using the text by Cantarow and Trumper as an authority, I would like to dispute this statement. This text lists as causes of hyperglycemia such diseases as syphilis of the central nervous system and increased intracranial pressure.

I presume that the misunderstanding is due to incorrect expression.

GLENN M. MORRIS, M.D., Assistant Resident Physician

The Norwegian Lutheran Deaconesses Home and Hospital Brooklyn, New York

Dr. Morris's letter was referred to Dr. Adams whose comment is as follows:

To the Editor The present opinion in most neurologic clinics is that the cerebrospinal fluid sugar closely parallels the level of blood sugar being elevated when the blood sugar is elevated and lowered when the blood sugar is lowered. The only exception to this is when bacteria or fungi are present in the cerebrospinal fluid. It follows from these facts, therefore, that one would expect the cerebrospinal fluid sugar to be elevated in untreated diabetes after a large dose of intravenous glucose and exceptionally when the walls of the third ventricle are damaged, as in a massive brain hemorrhage or other acute lesions in the same area. Certainly in our experience syphilis has no significant effect on the cerebrospinal fluid sugar nor does increased intracranial pressure.

RAYMOND D. ADAMS, M.D.

### DIAGNOSTIC PERICARDIAL TAPS

To the Editor From my hospital experience dating from 1910 I have observed that members of the medical staff in particular, are overcautious about performing diagnostic pericardial taps. They seem to be as fearful of resorting to that procedure as my teachers were about the aspiration of the knee joint. Today with the aid of x-ray films taken from different points and using both the recumbent and erect

positions it is quite unnecessary to wait for the development of the classic signs of pericarditis with effusion.

The actual danger of this simple test is insignificant. During my internship house officers could obtain the necessary rabbit serum for the prevailing treatment of certain hemorrhagic diseases only by aspirating blood from the hearts of the animals, appropriately anesthetized without especially suitable needles. In spite of the relatively small ventricles of the rabbit's heart, we were, with rare exception successful in withdrawing the usual amount of blood without the untoward death of the animal.

Paracentesis of the distended pericardium is not only of unique diagnostic value but also a prognostic and therapeutic aid both direct and indirect. With needles of a bevel no greater than that needed to penetrate the pericardium and with the choice of a site near the apex of the heart, there should be no incidental danger and no shock.

It is high time to dispel this bogey.

G. W. HAIGH, M.D.

242 Burncoat Street  
Worcester Massachusetts

### RH DETERMINATION A PUBLIC HEALTH FUNCTION?

To the Editor The editorial entitled "Threatened Curtailment of State Services" which appeared in the March 25 issue of the Journal and which recommended continued determination of Rh factor by the Department of Public Health has caused great concern and amazement among pathologists in and outside Massachusetts.

The editorial supports the concept of increasing socialization of medicine in one particular field of medical practice and encourages the invasion of the field of clinical pathology by state-supported laboratories. This tendency threatens the existence of the pathologist as a medical specialist; creates an uncertainty for the future of this branch of medicine and deters young graduates from specializing in it.

The determination of the Rh factor is a laboratory procedure that does not properly fall within the scope of a public health laboratory. Such determinations are now being capably performed in hospital and private laboratories throughout the Commonwealth under the supervision of pathologists. Potent and reliable antiserums are freely available; the technique is standardized and the determination by a trained technician is as accurate as an ordinary blood grouping. When special techniques or less commonly available antiserums are required recourse to freely accessible larger laboratories can readily solve the problems.

Although charges are properly made for the Rh determination in private and hospital laboratories, the pathologist recognizes his obligations to the patient and the test is done without charge whenever necessary.

The pathologist is peculiarly vulnerable to the inroads of socialized medicine. His future, however, is intimately related to that of all practicing physicians and invasions of his province should arouse the concern and support of the medical profession.

D. A. NICKERSON, M.D.

Salem Hospital  
Salem, Massachusetts

The changing concepts of what does and what does not constitute legitimate public health procedure have long been a subject of debate. All physicians will doubtless agree that the basic factor is the care of the patient. All opinion must eventually pass through this filter. — En

### DR. AUGUSTUS S. KNIGHT

To the Editor Dr. Augustus Smith Knight, Harvard A.B. 1887 and M.D. 1891 died in the Somerset Hospital, Somerville, New Jersey on March 21, 1948, after injuries received in an automobile collision. He was eighty-three years of age. Dr. Knight, who was born in Manchester, Massachusetts, received his early education in the public schools and at Phillips Andover Academy. He was popular as a student and generally liked by all who came in contact with him during his college years and afterward. He served as medical house officer at the Boston City Hospital in 1890 and 1891.

After graduation from Harvard Medical School he engaged in the practice of medicine at 1 Exeter Street, Boston and received an appointment as medical examiner in Boston for the Metropolitan Life Insurance Company of New York.

He was soon invited to New York as a subordinate examiner and here remained in the service to which he was so peculiarly adapted. His advance continued steadily until he was appointed medical director and a vice-president of the Company, remaining in the service until his retirement in 1934.

Dr Knight was also active in medical affairs in New Jersey, where he resided, and held affiliation with hospitals and important medical societies.

Dr Knight's first wife was his cousin, the former Abbie Knight, who died in 1929.

He is survived by his second wife, Anita Merle-Smith, to whom he was married in 1930, and by their son, Augustus S Knight, Jr.

He placed many younger doctors from Boston and the City Hospital in service for the Metropolitan Life Insurance Company in New York and elsewhere. To the writer of this note it is a most pleasant recollection to review his acquaintance and association with Gus Knight, particularly the memory of two summer months in 1890, when as medical students they lived together in harmonious service, gaining practical instruction in obstetrics in the outpatient department of the Boston Lying-in Hospital.

JOHN L. AMES, M.D.

Larchmont  
New York

## BOOK REVIEWS

*The Psycho-Analytical Approach to Juvenile Delinquency Theory case-studies treatment* By Kate Friedlander, M.D. (Berlin), L.R.C.P., L.R.C.S. (Edin.), D.P.M. (London), 8°, cloth, 296 pp. New York: International Universities Press, 1947. \$5.50.

On the premise that the fields of psychology, criminology and penology, and sociology have lacked co-ordination in their attempts to solve the problem of juvenile delinquency, the author aims to show the types of patients who can be aided by psychoanalysis with the combined co-operation in research by these scientific groups. The book is divided into three parts: factors responsible for the social adaptation of all persons, including the child's early relationship to his mother, the Oedipus conflict, the super-ego formation and group formation inside the family, the interaction of the state of "latent delinquency" with the various experiences discussed in the first part, which may lead to delinquent behavior, and the author's classification of juvenile delinquency as antisocial character formation, organic disturbances and psychotic ego-disturbance, and treatment and material on prevention and education of field workers. The treatment that is discussed as psychologic (psychoanalytic) is useful in handling patients with antisocial character formation and organic disturbances, and the environmental aspect is particularly necessary when delinquent behavior is due to antisocial character formation and when the home is "beyond repair." The author, in conclusion, summarizes a rational scheme for the prevention of crime, including abolition of factors leading to antisocial character formation with measures to be taken in the schools and after the school age, as well as when the young person comes before the court. This book should be of interest to all workers in the field of juvenile delinquency, although the psychoanalytic approach as yet is neither concrete nor expeditious enough to have very wide application. Each section of the book has a rich bibliography, and the case material is extensive, pertinent and well expressed.

*Ear, Nose and Throat Symptoms-diagnosis-treatment* By George D. Wolf, M.D. 8°, cloth, 523 pp., with 149 illustrations. Philadelphia: J. B. Lippincott Company, 1947. \$10.00.

The author attempts to present the common ailments of the ear, nose and throat by a classification of otolaryngologic symptoms. This modern presentation affords the student a very readable text printed on fine paper, in large print and well spaced. The approach shows the author's effort to fall in line with the current teaching emphasis on the symptomatic history as a most important aid in arriving at a diagnosis. However, the book demonstrates that it is quite impossible to execute his purpose. The text describes the physical findings quite accurately and lucidly and is similar

in content to other recent practical small editions on diseases of the ear, nose and throat. Certain specific statements made by the author are certainly open to criticism, examples of which are the following: "he [the author] has not encountered post-tonsillectomy bleeding if no aspirin is used" and "in the treatment of lateral sinus thrombosis, first ligate the jugular vein."

The many clear and self-explanatory sketches taken from Dr. Lyman Richards's textbook, *Otolaryngology in General Practice*, are excellent and of much aid in the material presentation.

The author briefly introduces the student and practitioner to otolastic and rhinoplastic procedures. Details are necessarily omitted in a compact volume such as this book is intended to be. The reference to endoscopy is also brief.

At the end of the book there are chapters on barotrauma and antibiotic therapy and, as a final chapter, the equipping of an otologist's office. A very liberal bibliography of current otolaryngologic literature has been utilized to bring the material up to date, and medical therapy is well covered.

*Medicine for Moderns The new science of psychosomatic medicine* By Frank G. Slaughter, M.D. 8°, cloth, 246 pp. New York: Julian Messner, Incorporated, 1947. \$3.50.

This is another medical book designed for the layman. The author is a well known novelist, in addition to being a well recognized surgeon. The reader can expect, therefore, interesting and dramatic presentation of the subject.

The volume is educational and attractively written. To mention only a few of the twenty-six chapters, particular attention is called to the following: "The Case of the Blushing Stomach," which describes the patient with peptic ulcer, "The Discontented Colon," which describes colitis and spastic colon, "Coronary Thrombosis The price of success" which correlates the disease and the personality, "My Love is Rosy Red," explaining the skin manifestations of emotions, and "The Reluctant Lover," which deals with repressions, frigidity, impotence and sexual deviation. Dr. Slaughter is a brave author, even to the extent of calling a chapter on socialized medicine "Revolution in Medicine."

No reader will agree with all his ideas. The reviewer notes the following contradictory statements: "This is the story of the new science of psychosomatic medicine" (Page 2), "Hippocrates undoubtedly recognized the necessity of treating both mind and body as a single unit" (Page 4) and "Psychosomatic medicine is not a new science." (Page 9).

On the whole this book is praiseworthy and, indeed, instructive. There should be more thought given to mental hygiene, some dogmatic statements are unhealthy, such as that on Page 71, "With a disease as important and as uniformly fatal as hypertension, it is natural that the problem of treatment should have been attacked from many angles." Is hypertension uniformly fatal? Perhaps the discussion of "high blood pressure" has done more harm than the disease.

This book should stimulate interest in medical progress which is surely a worthy cause.

## NOTICES

### ANNOUNCEMENTS

Drs. Henry J. Bakst and Harold L. Chandler announce their association for the practice of internal medicine at 48 Beacon Street, Boston.

Dr. Nathan Crosby Norcross announces the removal of his office to Medical Arts Center, 354 Hobart Street, Oakland, California, for the practice of neurological surgery.

Dr. Volta R. Hall announces the removal of his office to 422 Beacon Street, Boston.

Dr. Leon Ryack announces the removal of his office to 1093 Beacon Street, Brookline.

(Notices concluded on page xvii)

## NOTICES (Concluded from page 890)

## RESIDENCY IN RADIOLOGY

Applications will be considered for appointment for a residency in radiology at the Joseph H. Pratt Diagnostic Hospital and Boston Dispensary from physicians with one or two years training in radiology. There are about 24,000 diagnostic examinations yearly (medicine and pediatrics). There are also active services in the tumor clinic and therapy department and many teaching conferences. Appointments will be made for one year. Applications should be addressed to Mr. Richard T. Viguiera, Administrator, Joseph H. Pratt Diagnostic Hospital, 30 Bennett Street, Boston 11.

## FOCAL EPILEPSY\*

### A Statistical Study of Its Causes and the Results of Surgical Treatment

#### I Epilepsy Secondary to Intracranial Tumors

JAMES C. WHITE, M.D.,† CHING TUNG LIU, M.D.,‡ AND WILLIAM JASON MIXTER, M.D.§

BOSTON

THE neurologists and neurosurgeons of the Massachusetts General Hospital have long been interested in determining the causes of epileptic seizures in patients both acutely and chronically affected. Therefore, all epileptic patients admitted to the wards have been studied with special care for evidence of focal compression or scarring of the brain. Air studies by either pneumoencephalography or ventriculography, have been performed routinely in these patients, and electroencephalography since 1937. We have selected the decade 1935-1944 for statistical review because it gives a period extending from twelve to a minimum of two years for the evaluation of surgical results. These patients with seizures amenable to surgical treatment fall into two broad groups, depending on whether the epileptogenic discharge arises from the irritating action of an expanding lesion or a cortical scar.

#### MATERIAL

Of 1130 patients admitted to the Massachusetts General Hospital with all varieties of epilepsy in the 1935-1944 decade, 240 have had seizures<sup>¶</sup> arising from an area that could be localized by clinical signs, pneumography and electroencephalography. In all these cases the disease has been verified by exploratory craniotomy, the patients in whom a definite lesion could be found therefore comprise 21 per cent of the total admissions for epilepsy. For descriptive purposes we have divided this series into two groups: 160 cases of cerebral compression

caused by intracranial tumors and 80 cases of acute or chronic epilepsy due to trauma or infection. The first part of this paper concerns the relation of tumors of the brain to epilepsy, with a review of the cases on which we have satisfactory information. The results in a small number of other patients operated upon in this hospital, but not observed by any of us, are omitted from this statistical analysis. In a succeeding article, we shall discuss the production of convulsions secondary to intracranial injury or infection and the results of surgical intervention in this group.

When seizures are associated with an expanding tumor of the brain the convulsive state is usually set off by local irritation in the zone of compressed ischemic cortex. In the infiltrative tumors, particularly the glioblastoma multiforme, there is in addition more or less vascular thrombosis, which produces further necrosis of the cerebral gray and white matter in advance of the actual tumor. The source of the epileptic discharge is always found in the peripheral area of damaged brain—never in the electrically inert expanding tumor itself.

The 160 tumors giving rise to convulsive attacks may be subdivided according to their location above or below the tentorium, their compression of the brain from without or invasion from within and, to a lesser extent their proximity to the motor cortex. The relation of the position of the tumor to the incidence of complicating seizures is demonstrated in Table 1. The incidence of seizures is highest in tumors close to the motor sensory areas of the cerebral cortex, and the chances of epilepsy are about the same regardless of whether the tumor compresses the cortex from without or invades it from within. These findings corroborate the statements of Penfield, Erickson and Tarlov.<sup>1</sup>

The most striking feature of our statistics is the frequency of epileptic seizures in patients with brain tumor. Epilepsy occurred in 25% of

\*From the Neurosurgical Service, Massachusetts General Hospital.

§Member, Board of Consultation, Massachusetts General Hospital.

¶Although the type of epilepsy observed in the great majority of these patients was the classic Jacksonian focal seizure, some had generalized attacks and others only hallowatory auras. The petit mal form of epilepsy, however, rarely if ever starts from a superficial focus and is therefore not amenable to surgery.

641 patients with intracranial tumors operated upon during this period. In tumors of the cerebral hemispheres the incidence of seizures is as high as 34 per cent. This figure is lower than that given by Penfield and Erickson,<sup>2</sup> who record an over-all incidence of convulsive seizures in 37 per cent of all intracranial tumors and 45 per cent in the supratentorial cases. However, as the authors point out, others have reported an incidence of convulsions considerably closer to our figures. Thus, Sargent<sup>3</sup> gave a figure of 30 per cent after exclusion of pituitary and cerebellar tumors, Dowman and Smith<sup>4</sup> one of 39 per cent with some form of epileptiform seizure, Parker<sup>5</sup> 21.6 per cent of focal seizures, Fur-

order of the type of their attacks) leads to the following conclusions:

One patient (M T), with an acoustic neuroma, suffered from typical ictus subtentorialis as described by Penfield and Erickson.<sup>2</sup> She had syncopal attacks in which she became dizzy and collapsed, losing consciousness for a few minutes. At these times she often "became stiff all over" (tonic postural seizures). After subtotal removal of the tumor she remained free of seizures for three years.

Another patient (S S) suffered from episodes of vertigo with staggering to the left followed by

low and Sachs<sup>6</sup> 31.4 per cent among 248 verified intracranial lesions, and Pedersen<sup>7</sup> 29 per cent of 586 verified tumors.

Our finding of 7 cases of epilepsy among 125 infratentorial neoplasms is in fairly close agreement with the 3 per cent incidence reported by Penfield and Erickson<sup>2</sup> from the Montreal Neurological Institute. These writers have stated categorically that true epilepsy cannot result from a lesion limited to the posterior fossa, but that tumors compressing the lower brain stem and cerebellum may lead to what they have termed "ictus subtentorialis." Episodes of this sort consist of irritative stimulation of the lower cranial nerves, transient vertigo and syncope, in addition to tonic postural seizures with extensor rigidity and opisthotonos. On the other hand, Hoefer et al.,<sup>8</sup> in a review of a series of brain tumors at the New York Neurological Institute, have described 5 cases of posterior-fossa neoplasms that they considered to be the cause of true epileptiform attacks.

A review of the seizures that occurred in our 7 patients (not in chronological sequence, but in

several syncopal attacks, during which his parents observed no convulsive movements. At operation this nineteen-year-old boy was found to have a large medulloblastoma. After intensive radiation he began to have generalized seizures in his sleep, but on medication these have ceased during the past sixteen months. As Penfield and Erickson<sup>2</sup> have pointed out, a tumor of this type may metastasize via the subarachnoid space and give rise to true epilepsy by the development of a cortical focus.

A third patient (E S), with a large acoustic neuroma, suffered from intense vertigo and periods of syncope. A single generalized convulsive seizure was witnessed a month after operation.

In another case of acoustic neuroma the seizures developed only after operation and discharge from the hospital. As no accurate description of these spells could be obtained through the Social Service Department, it is impossible to draw any conclusions from this case.

The fifth patient (D B) had attacks of cerebellar vertigo. In addition there were seizures in

which the right arm was thrust out but did not shake, accompanied by transient loss of consciousness. This patient was an athletic young woman who also gave a history of several head injuries incurred while she was riding and diving, it is therefore conceivable that she had a traumatic focus in the cerebral cortex as well. At operation a midline necrotic tumor was biopsied that had the gross appearance of a medulloblastoma but on histologic examination could not be classified.

A child of two years (J D) developed attacks of syncope and rigidity in addition to several generalized seizures. These episodes of syncope were indistinguishable from certain forms of petit mal, which occur in persons without any suggestion of infratentorial lesion, and were accompanied by brain waves with the wave-spike contour. Evaluation of the origin of these seizures was further complicated by the fact that this child also suffered from hypoglycemia, with a blood sugar on several occasions below 50 mg per 100 cc. At operation a midline cystic astrocytoma was found, with separation of the cerebellar hemispheres.

In the last patient (A L) a hemangioma of the choroid plexus was partially removed from the fourth ventricle and may well have extended up the ventricular system above the tentorium. He had major seizures, with tonic stiffening of the left leg.

Electroencephalograms were done on only 4 of these 7 patients. The other 3 were cared for before the advent of routine testing. The brain waves were of the fast normal type in the patient with unequivocal ictus subtonialis of the syncopal and tonic postural types (M T). The presence of wave-spike activity has already been mentioned in the child who may have had true ictus subtonialis (J D). The electroencephalogram in the second patient (S S) was abnormal and indicated diffuse, widely scattered slow activity. Seizures in the fourth patient did not begin until after operation and discharge. The preoperative electroencephalogram showed diffuse moderate slowing.

Hoefer, Schlesinger and Pennes,<sup>3</sup> who have recently gone over the statistics from the New York Neurological Institute, give an over-all incidence of 30 per cent of epilepsy in their series of 595 cases of brain tumor. Excluding their infratentorial and midline lesions, a third of the tumors invading the hemispheres led to epilepsy. The greater incidence of seizures in the Montreal series may be explained by Dr. Penfield's well known interest in epilepsy. Considering all the above figures, it seems fair to say that seizures occur in nearly a third of all intracranial tumors.

Our experience, therefore, corroborates the statements of Penfield and Erickson,<sup>4</sup> who believe that

no typical epileptic seizure can result from a lesion limited to the cerebellar cortex or brain stem. These authorities cite the fact that it is impossible to induce convulsive seizures by electrical stimulation of these structures. Of their 4 cases of infratentorial tumor with major seizures of the type generally

FIGURE 1 Relation of Age to Incidence of Epilepsy

recognized as cerebral in origin, 2 were due to medulloblastoma with metastatic lesions in the cerebral hemispheres. In another case the seizures were explained by cortical compression from ad-

FIGURE 2 Incidence of Seizures among Patients with the Principal Supratentorial Tumors

vanced hydrocephalus, and in the fourth by concomitant idiopathic epilepsy. Ictus infratentorialis is therefore a warning signal of serious compression of the brain stem. These attacks involving the lower cranial nerves, often accompanied by transient vertigo and syncope, as well as tonic postural seizures with extensor rigidity and opisthotonos, are caused

by irritative stimulation of the medullary and adjacent structures

In our experience, as in that of Penfield and Erickson,<sup>2</sup> deeply situated tumors in the basal ganglia and third ventricle rarely gave rise to seizures (Table 1). We have encountered no case of "diencephalic epilepsy" similar to that described by Penfield.<sup>9</sup> Typical epilepsv is also rare in the

Since the great proportion of seizures due to birth injury or idiopathic epilepsy start in childhood or early adult life, it can be stated that *when epilepsy begins in adult life without a previous history of cranial trauma, cerebral abscess or encephalitis, the most probable diagnosis is tumor of the brain*

The type of lesion is a matter of further importance in the genesis of convulsions. The cytologic origin and the intracerebral or extracerebral situation of the common malignant and benign tumors located above the tentorium are shown in Figure 2, study of which reveals that the greatest incidence of epilepsy occurs in association with the astrocytic tumors of the glioma group and with the meningiomas. In the lesions that invade the hemisphere diffusely the lowest proportion is in the glioblastoma multiforme and metastatic carcinoma. As already pointed out by Penfield and Erickson,<sup>2</sup> the more slowly the tumor grows, the greater its epileptogenic tendency is likely to be.

#### RESULTS OF OPERATION

For the neurosurgeon who has to operate on these patients and also for the physician who refers the patient to him, the primary concern is to save or prolong life by radical resection. The fact that epileptiform seizures may continue, even after apparent total removal of a meningioma or cystic astrocytoma, is often lost sight of. So is the fact that, after resection, epilepsy may develop later when none existed before the operation. Because of the patient's gratitude that his life has been spared and because these seizures are often mild, this fact has seldom been emphasized. It is well, however, to realize this unpleasant possibility. Over-all statistics, which cover these points, are given in Table 2 and in the following paragraphs.

To express more clearly the effect of surgery on the epileptic complications of intracranial tumors, a brief summary of each of the more frequent varieties is included.

#### Astrocytoma

These gliomas may invade the brain diffusely or may remain partly encapsulated growths. The most favorable types are cystic and may contain only a small area of active tumor. These are generally limited to children and do not cause epilepsy because they characteristically occur in the cerebellum. Unfortunately, the epileptogenic astrocytomas of the hemisphere are most often the diffuse variety in which total extirpation is usually out of the question. In our series, as in that of Penfield and Erickson,<sup>2</sup> astrocytoma is the tumor that most frequently leads to epilepsy. In this ten-year period we have operated on 88 patients of this group, exactly half of whom had accompanying epilepsy. Sixty-nine of these astrocytomas lay above the tentorium, with a seizure rate of 62 per cent. In 3 out of 4 the onset of seizures had been the first

FIGURE 3 *Astrocytoma Presenting in the Left Frontoparietal Cortex*

*This forty-four-year-old woman gave a ten-year history of right-sided Jacksonian seizures. She had only recently developed mild aphasia and right hemiparesis. Partial resection of a deeply invasive tumor was done in 1939, after which there was improvement in speech and hemiparesis for two years, but seizures were only slightly reduced. She died four years after operation and fourteen years after the onset of epilepsy.*

pituitary adenomas, unless they have escaped from the sella and are expanding upward between the hemispheres or laterally into the temporal lobe (Jefferson<sup>10</sup> and White and Warren<sup>11</sup>).

Another important factor in the relation between tumor and epilepsy is the age of the patient, since the greater proportion of brain tumors in children invade the cerebellum and brain stem, where the tendency to produce seizures is at its lowest (Fig. 1).

suggestion of disease, often antedating any other evidence of the expanding intracranial mass by a period of months or even years. The following case report is of interest in this connection, especially as it refutes the commonly accepted rule that a normal pneumogram precludes the presence of a brain tumor.

A 40-year-old traveling salesman suffered his first seizure after becoming intoxicated at a business banquet in Boston. He was examined by Dr. Stanley Cobb, who found no evi-

as the first sign of disease in 75 per cent. Figure 4 illustrates a typical tumor of this sort. Both the glioblastoma and the astrocytoma diffusum invade the brain so extensively that there is seldom any chance of total resection and cure. Whereas extensive, although partial, removal of the larger astrocytomas may lead to considerable improvement of epilepsy, the results in this most malignant type of glioma have been all but worthless, only 1 out of 19 patients showing any improvement. Epilepsy not

\*Patients listed as "cured" had no seizures after discharge from the hospital. Those listed as "greatly improved" had only very rare spells, and rarely long periods with complete freedom from attacks; they considered their results excellent and were all able to lead relatively normal lives.

†This group includes the craniofibrogliomas, epidermoids and dermoids.

dence of increased intracranial pressure and no abnormal neurologic signs. A pneumoencephalogram revealed no deformity in the well filled ventricles or subarachnoid space. A year later at a similar business convention in Minnesota the patient suffered a second series of seizures. Pneumography repeated at the Mayo Clinic showed a definite filling defect, and Dr. W. McK. Craig was able to remove a large amount of astrocytoma from the left frontoparietal area.

In our 33 patients who were operated upon and adequately followed, the incidence and severity of seizures have been reduced in 8, so that 6 have been able to return to work, 22 have been unimproved. Not one has been completely freed of seizures. Epilepsy, not present before operation, has developed subsequently in 3 cases. The reason for these poor results, so far as the seizures are concerned, is inherent in the invasive character of many of the tumors and the tendency for those which most frequently give rise to seizures to involve vital areas of the brain. A typical tumor of this type (Fig. 3) shows the difficulties of relieving these patients of their seizures, although the duration of life may be greatly prolonged.

#### Glioblastoma Multiforme

In 145 glioblastomas encountered in this decade, 32 (22 per cent) were productive of seizures. In cases in which seizures were present they occurred

present before operation developed subsequently in only 1 case.

#### Oligodendroglioma

We have encountered only 19 examples of this glioma, which in its rate of growth is situated midway between the astrocytoma and the glioblastoma. Seven gave rise to seizures (37 per cent). Only 4 of these are suitable for evaluation, with much improvement in 2, and no reduction of the seizures in the others.

Among the other varieties of glomatous tumors our material is too limited to draw any definite conclusions, but the figures are included in Table 2.

#### Meningioma

It is not surprising that this slowly growing tumor, which arises from the meninges and causes local compression of the brain, should be a frequent cause of convulsive manifestations. This was true in 35 of our 99 cases. In these, seizures were the primary symptom in 47 per cent. In the series from the Montreal Neurological Institute 67 per cent of the growths were associated with epilepsy, and this incidence was almost the same as that with astrocytoma. In the New York series of Hoefel et al. 46 per cent of the patients with astrocytomas

suffered from seizures, as against 37 per cent of those with meningiomas. Our series is comparable to the latter, 35 per cent being productive of seizures, as against 50 per cent of the astrocytomas. Unfortunately, Cushing and Eisenhardt<sup>12</sup> gave no over-all

result because the patient had a few minor seizures two years after the operation when she got overtired. There have been no further attacks, the area of decompression remains soft, and she is able to lead a perfectly normal life.

In the 26 cases with seizures in which adequate follow-up observations are available, 5 patients have had complete relief, 9 great improvement, and 3 only slight benefit, whereas in 4 the convulsive state has continued, even though removal appeared complete in all but 1. Five others developed their first seizures after what appeared to be successful extirpations. All these postoperative seizures were successfully controlled with medication. In the series reported by Groff<sup>13</sup> from the University of

FIGURE 4 Left Temporoparietal Glioblastoma Multiforme in a Forty-Eight-Year-Old Man with a One-Month History of Aphasia, Right Hemiparesis and Jacksonian Seizures, Which Began in His Arm.

Operation resulted in no improvement, and the patient died four months later.

FIGURE 5 Left Parasagittal Meningioma in a Forty-Three-Year-Old Woman with a History of Intermittent Episodes of Paresthesia in the Right Arm for Four Years, Followed by Jacksonian Seizures of Two Years' Duration.

She described these attacks as beginning with a cold, numb feeling in the right arm and hand, followed by acute pain with tonic flexion of the fingers. This sensory aura spread down the right side. As the foot became involved the patient lost consciousness and had a typical major seizure. After removal of the tumor in 1939 the patient has remained well and free of seizures to date.

figures for the incidence of epilepsy in their great series of meningiomas, although they commented on the fact that the continuance of seizures after removal of the tumor was often "highly disconcerting."

Figure 5 illustrates a large parasagittal meningioma, which produced severe compression of the sensory-motor cortex with frequent epileptic seizures. Total extirpation of the growth, as shown in this photograph, has resulted in a seven-year period of improvement. This case is not listed as a perfect

Pennsylvania and also those by Penfield, Erickson and Tarlov<sup>1</sup> the incidence of seizures postoperatively was quite similar. In explanation of the continued attacks and the postoperative onset of seizures Penfield et al. state

Even an encapsulated meningeal fibroblastoma removed with meticulous care, usually leaves behind it, in the area of maximum impingement on the brain injury or absence of pia mater. This results in scar and continuing abnormality of cortical circulation.

### Metastatic Carcinoma

Only 5 out of 35 patients with carcinomatous metastases had accompanying seizures. In 4 cases, in which the lesion appeared to be well demarcated and was thought to have been "totally" excised, no lasting improvement followed. These patients may well have had other metastases, or the lesion may have rapidly recurred. Figure 6 illustrates this condition in a forty-three-year-old woman with primary bronchogenic carcinoma. The seizures always began with a sensation of tingling in the fingers of the left hand, and the electroencephalogram showed a small localized focus of cortical dysfunction in the midline just posterior to the junction of the coronal with the sagittal suture. Intracranial pressure was not elevated, and the pneumoencephalogram showed only a minimal deformity of the right lateral ventricle. In a later ventriculogram there was an added suggestive filling defect at the tip of the right ventricle, so that the patient may well have had a second metastatic tumor. The mass infiltrating the sensory cortex (Fig. 6) was excised with a wide margin. Although she never had any further seizures, she was reported to be having signs of recurrence within the brief period of two months, and she died four months after operation.

### Pituitary Adenoma

In our series of 24 pituitary tumors only 2 patients have exhibited epilepsy. One of these was seen in a Navy hospital, and this case has been reported because of the unusual size of the tumor.<sup>11</sup> In these 2 patients with seizures, as emphasized by Jefferson,<sup>10</sup> the chromophobe adenomas had expanded far beyond the usual confines of these lesions. The smaller had grown directly upward and was compressing the chiasm and floor of the third ventricle from below. Subtotal resection resulted in only slight temporary improvement, and the patient died of a recurrence three years later. In the other patient, who entered the hospital in status epilepticus, the tumor was so extensive that only a relatively small portion could be removed. At post-mortem examination this patient was found to have a chromophobe adenoma weighing 150 gm. and extending backward beneath the brain from the tip of the anterior fossa to the mid-pons. When epilepsy is seen in conjunction with an adenoma of the pituitary body, it is a danger signal indicating that the tumor is expanding widely beyond the sella turcica.

### Tumors of Blood Vessels

Thirty-three tumors of the cerebral blood vessels are listed in Table 2, of which 11 gave rise to seizures.

Histologically they fall into two groups, the deep hemangiomas composed of small vessels and the larger caliber angiomas or racemose aneurysms. The capillary hemangiomas, especially the cystic type seen in Lindau's disease, usually occur in the cerebellum and are therefore not a common cause of seizures. We have encountered 11 cases of noncystic

FIGURE 6. Carcinoma of the Bronchus with Metastasis to the Right Parietal Cortex.

A history of weakness of the left arm of four months' duration was presented. Jacksonian seizures began with an aura of tingling in the fourth and fifth fingers of the left hand. Operation in 1938 with electrical stimulation of cortex and resection of a small superficial metastatic tumor. Seizures ceased after operation but the patient progressively failed, dying in four months.

A = Rolandic vein and B = Carcinomatous infiltration of pia (see marker No. 3 in photograph). 3—alt. 60-cycle stimulus at marker No. 1 caused tingling in the little and ring fingers; at No. 2, tingling in the thumb and index finger; at No. 4 contraction of the hand and index finger; at No. 5 contraction of the orbicularis oculi and at No. 6 contraction of the hip.

cavernous hemangiomas in the cerebral hemispheres, 6 of which gave rise to seizures. These were explored and extensive resections carried out in 2 patients, both of whom improved so that, despite very minor seizures, one was able to return to school and the other has been working full time as a lawyer for ten years. Of 2 others in whom only biopsy was performed followed by radiation one was greatly improved at five years, and the other not benefited.

One patient died after exposure of the tumor in the fourth ventricle. In the remaining case the tumor was not found at operation, but when post-mortem examination was performed eight months later a deep frontoparietal hemangioma was disclosed.

The superficial angiomas producing arteriovenous cirroid aneurysms of the cortical blood vessels (Fig

periods of five to six years in 2 others, whereas the fourth derived only slight benefit. In the fifth case, a baby, the mass of dilated vessels in the temporal lobe was decompressed, but the period of postoperative observation was too short for evaluation of the effect.

#### SUMMARY

It is apparent from this review that epilepsy is a very common complication of brain tumors, accompanying approximately 1 out of every 3 such growths when the hemispheres are compressed or invaded. When a middle-aged patient complains of epilepsy of recent onset, occurring without previous history of trauma or infection, tumor of the brain is the most probable diagnosis. The victim of this disease is actually fortunate if it begins in this fashion, for statistical evidence indicates that the tumor with accompanying early seizures is most likely to be growing slowly and situated near the surface of the hemisphere, either a meningioma or astrocytoma or an oligodendroglioma. If attention is paid to this important sign, an early search can be made for the lesion, and radical excision attempted before the patient has reached the critical advanced stage of the disease. Chances of "curing" the convulsive state, however, are not very good. Of the most common examples, 17 out of 26 patients with meningiomas have been improved, and 5 of these apparently cured of their seizures. Four failed to derive any benefit from total removal of the tumor, and 5 developed the first seizures after an apparently successful resection. In 33 cases of astrocytoma no patient has had an apparent cure, and in only 8 have the frequency and severity of the seizures been significantly reduced. Epileptic convulsions have continued in the remaining 22, owing to the surgical difficulty of totally eradicating the diffusely invasive forms of astrocytoma or avoiding the irritative action of the contracting scar after radical removal of these tumors. Three others suffered their first convulsions after operation. In 2 out of 4 patients with oligodendrogliomas, 1 has been entirely relieved of his seizures and the other greatly improved. In the more malignant glioblastoma multiforme and metastatic carcinoma of the brain we have no right to claim any definite benefit of more than a few months' duration. Epilepsy associated with other forms of intracranial tumors occurred in too few patients to permit deductions of any significance.

Lesions of the basal ganglions and third ventricle are infrequently a cause of epilepsy. When this complication is associated with pituitary adenomas it is a nearly certain sign that the tumor has expanded widely out of its usual site.

In our experience tumors that are definitely limited to the posterior fossa and have no other complicating factor usually produce atypical seizures associated with transitory attacks of vertigo, syncope and irritation of the lower cranial nerves. This

FIGURE 7 Angioma or Cirroid Aneurysm of the Left Parietal Cortex in a Thirty-Three-Year-Old Man Who had Noticed Numbness and Stiffness of the Right Arm and Hand for One Year, Followed Shortly by Jacksonian Seizures

Exploratory craniotomy in 1940 was followed by radiation therapy. Seizures improved, but recurred with heavy drinking, which necessitated commitment to an institution. Epilepsy was then controlled with anticonvulsant drugs, but he died four years later of tuberculosis with massive pulmonary hemorrhage.

7) are generally inoperable because of their extreme vascularity and the damage to the circulation of the brain that would result if extirpation were attempted. Radiation, however, which followed exploratory craniotomy in 4 cases, resulted in a five-year cessation of seizures in 1 and great improvement for

syndrome, classified as "ictus subtentorialis," is caused by compression of the pons or medulla. In the rare case in which typical major seizures occur, it is usually found that a medulloblastoma has implanted itself above the tentorium or that there is some other explanation.

This investigation was supported by a grant from a medical foundation that wishes to remain anonymous.

## SWIMMING POOLS\*

### Their Relation to Illness

J. ROSWELL GALLAGHER, M.D.†

ANDOVER, MASSACHUSETTS

DURING the seven years 1941 to 1947 reasonably accurate records of swimming-pool attendance and of the incidence of respiratory-tract and communicable diseases have been kept at a boys' boarding school in Massachusetts for the purpose of determining whether a difference in frequency of these illnesses existed between those who used and those who did not use the swimming pool. Only boarding students have been considered in these records because of the difficulty of accurately determining the nature of all day students' illnesses. At this institution the season for competitive swimming and swimming-team training extends from the middle of November through the first week of March, but because of the changes in team personnel that occur during the early part of the season and because of the difficulty of assessing the duration of illnesses occurring prior to the Christmas holidays, this study covers only the winter term portion of the swimming season (approximately, the eight weeks subsequent to the first week of January). The interval studied is brief, but it is the period during which respiratory and communicable diseases are at their height, and any differences in incidence in these illnesses between boys who do and those who do not go into the pool should be accentuated at that time.

The swimming pool at this institution is equipped with a filtration and chlorination system. The chlorine level, reaction and bacterial content are determined frequently and have always been maintained at highly satisfactory standards. It has

been the policy immediately to close the pool for a short time should the chlorine level become either too high or too low or should any highly contagious and serious illness (such as a meningococcal infection) develop among the swimmers. It has also been the policy to exclude from the swimming group any boys whose past history indicates a marked susceptibility to infections of the middle ear or nasal sinuses<sup>1,2</sup>; this policy, however, has not been an ultraconservative one, and those who are alleged previously to have had frequent attacks of sinusitis but whose general condition is good are frequently permitted to elect this sport on a trial basis. No students except those regularly enrolled on the swimming squad are permitted to use the swimming pool during the winter term; this regulation is made not only to prevent overcrowding the pool but also to allow a better control of illness by confining the use of the pool to boys well known to the coaches. All swimmers are strongly advised against going into the pool when they have any symptoms of an upper-respiratory-tract infection, and the coaches have been alert and co-operative in enforcing this advice. To prevent malingering among and chiefly to maintain the condition of swimmers an exercise program called "dry swimming" is provided for all swimmers on days when minor-upper respiratory tract infections prohibit their going into the pool but do not contraindicate their having sufficient exercise to maintain their level of endurance and muscle tone. Such a supplementary exercise program is essential if one is properly to enforce a regulation that none with "colds" may swim, and

\*From the Department of Health, Phillips Academy School of Medicine, Phillips Academy.

at the same time both avoid malingering on this basis and prevent a deterioration in a swimmer's condition from lack of exercise. Strenuous exercise during the early stages of a severe common cold is not advocated, there is, however, a serious attempt to avoid the attitude that is rightly re-

ports of the incidence of respiratory-tract infections and the common communicable diseases over a period of the winter terms from 1941 to 1947 are presented below. There are also data concerning the number of admissions to the school hospital and the number of days spent in the hos-

\*Only admissions for diseases of the respiratory tract are considered

ferred to as the "abuse of rest." In my opinion athletes are "strained" or harmed by exercise only when they put forth strenuous exertion for which they have not been conditioned properly.<sup>4, 5</sup>

In this report three classes of students are considered: those who did not go into the swimming pool at all during the winter term (these are referred to as "nonswimmers," but this does not mean that they were unable to swim), those who went into the pool no more than seven times during the winter term (these are referred to as "occasional swimmers"), and those who elected swimming as their form of athletics for the winter term and whose attendance was regular except for such a

hospital. The main purpose has been to attempt to determine whether there is any significant difference in incidence of illness between boys who swim in an indoor chlorinated pool during a New England winter and those who do not do so. The category of "occasional swimmers" exists only because it did not seem proper to include students who went into the pool on the average only two or three times with those who swam regularly all term, and because it was obviously improper to classify them with the group made up of those who did not go into the pool at all. This discussion, for the most part, concerns a comparison of the "regular swimmers" and the "nonswimmers",

reason as illness (these are referred to as "regular swimmers"). The "occasional swimmers" consisted of those who preferred to change to some other sport early in the term or those who became ill early in the term and did not subsequently return to swimming.

the "occasional swimmers" because of their small numbers are referred to only in Table 1. The data in Table 1 indicate that over the winter terms of the seven years from 1941 to 1947 there was a slightly larger number of hospital admissions per boy on account of respiratory illness.

in the group of regular swimmers than in the other groups, except for one year (1945), when the incidence of this type of disease was at its lowest for the period studied. The average number of admissions for the seven years was about 14 per cent greater for the regular swimmers than for the others. The differences between these groups are slight, and it may be that illness was not even this much more frequent in the group of "regular swimmers"

such as influenza and hemolytic streptococcus pharyngitis would be expected to spread more widely among the swimmers, but they do not always do so. In 1941 the number of cases of influenza within the swimming group was 10 and that among the nonswimmers 78 (about 1.6 times as high a rate for the latter), but in 1946 there were 24 cases against 73, making the incidence 1.2 times higher in the swimming group. In 1945 the small total

but that the swimming coaches, being more conscious than other coaches of the effect of their sport upon respiratory disease, were more apt to send their boys to the school hospital. The variation in incidence of this type of illness from year to year (from 0.14 to 0.77 admissions per boy among the swimmers) indicates that conclusions are unre-

number of cases (12) makes the much higher incidence (over three times the frequency for swimmers) among the nonswimmers of little significance. During none of these winter terms was hemolytic streptococcus infection very prevalent—in 1946 5 of the 12 cases of pharyngitis from this source occurred in the swimming group, a frequency three

liable unless they are based on data collected over a period of several consecutive years.

The frequency of several of the respiratory tract illnesses is shown in Table 2. Common colds and acute pharyngitis were somewhat more prevalent (10 and 20 per cent respectively) among the swimmers than among the nonswimmers, and primary atypical pneumonia (of which there were only 27 cases within these two groups in seven years) occurred about three times as frequently among the nonswimmers. Diseases of high communicability,

times as great as that among the nonswimmers. There was no difference in the incidence of otitis media in the two groups for the entire period, but the rate for the small number of cases of acute sinusitis was almost twice as high among the swimmers.

There was not a large number of cases of the common contagious diseases in the student population during the seven-year period studied (Table 3). The number of scarlet-fever cases was small, and it is probably only due to chance and the small

number of cases that all these are found in the non-swimmers. Chance again probably explains the fact that although there were 9 cases of chicken pox in 1942 and 11 cases in 1944 among the non-swimmers, no cases appeared among the swimmers, since no initial case developed in a swimmer,

TABLE 5 *Number of Hospital Days per Boy for Each of the Winter Terms, 1941-1947\**

1947	0 75	0 99
Averages	2 14	2 09

\*This table includes admissions for all types of disorders (respiratory, gastrointestinal, surgical, psychiatric and so forth)

there was no opportunity for contagion in the swimming-pool situation. The findings regarding mumps and measles, however, were quite different, and are of interest because of the fact that their viruses are found in mouth and nose washings. In 1941 there were 48 cases of measles among the non-

only the incidence of various respiratory illnesses within the swimming group but also the number of days spent in the hospital for these and other types of illness or injury. The sport may be more of a hazard to classroom attendance on the basis of a higher incidence of respiratory illness and the common contagious diseases but no more of a one from the standpoint of number of days lost because of these disorders. It is further possible that the days lost from *all* types of illness or injury may be no higher for the swimming group than for the nonswimmers; it is conceivable that the higher incidence of respiratory-tract and common contagious disease among the swimmers might be balanced by a higher incidence of other types of ailments in nonswimmers. Data giving the number of hospital days spent only because of respiratory-tract illness are presented in Table 4. The group that did not go into the swimming pool at all averaged, over this period of six winters, about 14 per cent fewer hospital days on account of respiratory illness than the group that swam regularly. In only two years was the number of hospital days lower for the swimmers than for the nonswimmers, but in the year 1946, in which the incidence of respiratory illness was the highest for this six-year period (Table 1), there were only slight differences

\*In 1941 respiratory illnesses accounted for 82 per cent of hospital admissions among swimmers, and miscellaneous disorders and so forth for 2 5 per cent.

swimmers and a third more per boy among the swimmers. In 1943 there were 5 cases of mumps among the nonswimmers and six times as many per boy among the regular swimmers. When the number of cases is small, it is always difficult to determine the influence of chance, but these figures seem to be of some significance. In the presence of an initial case within a swimming group the possibility for the spread of measles and mumps seems to be much greater than that within a group not using a swimming pool.

One of the chief functions of a student health service is to keep students well and at their classes, the effect of any aspect of school life upon classroom attendance has to be considered and evaluated. Therefore, it is of interest to determine not

between the incidence and the hospital-day figures for these two groups.

It appears that other types of illness and injuries are a sufficient factor in the number of hospital days spent so that despite the higher incidence of respiratory illness among swimmers their average days spent in the hospital *from all causes* is only 2 per cent higher than that for the nonswimmers (Table 5). In four of the seven years the average number of hospital days was smaller for the swimmers than for the nonswimmers, and again the considerable year-to-year differences emphasize the need of extending such observations over a period of several years. The data in Table 6, showing the percentage of *all* admissions due to respiratory tract disease, suggest how this can be true, but

why there should be a lower percentage of admissions for other than respiratory or the common contagious diseases among the swimmers in each of the seven years is not clear. One factor may be the very low incidence of injuries at swimming as contrasted to other winter sports. In six consecutive years there was a total of four injuries at swimming,\* and in this period there were about ten times as many injuries per participant in such sport as wrestling and basketball as there were in swimming.

### SUMMARY

A comparison of the illnesses that developed among students at a boys' boarding school who used the swimming pool with those who did not do so indicates that in the seven-year period studied there was a higher incidence of respiratory illness among the swimmers. The number of hospital days spent because of respiratory-tract illness and the number of hospital admissions for the same cause were both about 14 per cent greater among the swimmers than among those who did not use the pool. There was, however, considerable yearly variation in both the incidence and the number of hospital days spent for this type of illness and it is clear that this does no more than reiterate the need for careful supervision of both pools and bathers so that excessive respiratory illness may be avoided. When careful control is exercised and

when normal conditions exist, there is on the basis of this experience, no reason to expect a high incidence of respiratory infection among swimmers. In the presence of a highly communicable disease, however, these data suggest that it is desirable to take extra precautions in this group. Mumps and measles seemed to spread more rapidly among the swimmers.

The number of hospital days spent for all causes was, over this seven-year period, practically the same for the swimmers as it was for those who did not go into the pool, the higher incidence of respiratory illness among the swimmers was balanced by a higher incidence of injuries and other ailments among the others.

In the presence of careful control and reasonable precautions it does not appear that the benefits of this swimming pool were overbalanced by its effect upon either the frequency or the duration of illness.

## MYCOTIC ANEURYSM OF THE BRACHIAL ARTERY AFTER CURE OF BACTERIAL ENDOCARDITIS\*

### Successful Treatment by Surgical Excision

ALFRED HURWITZ, M.D.,† AND DANIEL B. ARST, M.D.‡

NEWINGTON, CONNECTICUT

THE occurrence of mycotic aneurysm secondary to bacterial endocarditis is comparatively rare. In 1923 Stengel and Wolferth<sup>1</sup> reviewed 217 cases, 187 of which had associated bacterial endocarditis. The sites of predilection were as follows: aorta, 66, superior mesenteric artery, 24, hepatic artery, 19, femoral artery, 16, splenic artery, 15, middle cerebral artery, 14, other intracranial arteries, 14 and brachial artery, 10. The authors pointed out that the most frequent sources of the primary infection, other than the heart, were located in the lung and in bone. Several attempts had been made to ligate

or to remove mycotic aneurysms but, according to these authors, "A considerable number of patients have died as a result of the operation or their death has apparently been hastened by it, and even those who recovered with a good local result usually died within a short time from their cardiac infection." This pessimistic attitude is no longer warranted in view of the high percentage of cures now obtained in the treatment of bacterial endocarditis with antibiotics. In a series of 44 patients treated with penicillin, Paul, Bland and White<sup>2</sup> reported cures in 29 (66 per cent). In 2 of the cases in which the treatment was a failure the patients died of ruptured mycotic intracranial aneurysms, and in 1 of these, cultures from the involved aortic valve and the heart's blood were sterile. It was postulated that the aneurysm, although sterile at the time of post-mortem examination, had developed as a result of previous weakening of the

vessel wall by bacterial implantation before the blood stream had been effectively sterilized

Klein and Crowell<sup>2</sup> reported a cure with penicillin in a patient with endocarditis due to *Streptococcus viridans*. They successfully extirpated an aneurysm that had developed in the right ulnar artery just below the elbow.

The following is a report of another successful removal of a mycotic aneurysm that developed in the left brachial artery of a patient with endocarditis due to a Type VIII pneumococcus

### CASE REPORT

R L M, a 20-year-old, unemployed veteran of World War II, was admitted to the hospital on July 21, 1947, with the chief complaints of headache, stiff neck, chills and fever. He had had intermittent nasal obstruction and symptoms suggestive of sinusitis since a fracture of the nose in 1945. In April, 1947, a submucous resection was done. Physical examination at that time revealed no cardiac abnormalities. Because of the recurrence of sinusitis, the patient had quit his job in an asphalt plant about 1 month prior to admission. Nineteen days before admission he developed mild frontal headache and later, ill defined, migratory pains in the chest and abdomen. These symptoms continued in spite of treatment with nose drops and sulfadiazine. Two weeks before admission, he had chills, fever, nausea and vomiting, which also failed to respond to sulfadiazine therapy. On July 19, he was admitted to a hospital in another city, where he was found to have fever, a cardiac murmur and nuchal rigidity. He was transferred to this hospital.

Careful questioning of both the patient and his mother failed to elicit any past history suggestive of rheumatic fever or other serious childhood illnesses except for "pleurisy" at the age of 14, when he had been hospitalized for 1 week.

Physical examination disclosed a patient who was acutely ill and drowsy but well oriented and complaining only of headache and stiff neck. There was moderate nuchal rigidity, but there was no Kernig or Brudzinski sign. Periorbital edema was the only ocular abnormality. The pharynx and nasal mucosa were injected, and there was a moderate amount of mucopurulent post-nasal discharge. The lungs were normal to percussion and auscultation. Auscultation of the heart revealed a loud, rough, apical systolic murmur poorly transmitted to the left axilla and no diastolic murmur. There was no cardiac enlargement. The spleen was easily felt just below the left costal margin. The left ankle was slightly tender, but there was no swelling or erythema. There was mild clubbing of the fingers and cyanosis of the nails. There were no petechiae or skin changes and no lymphadenopathy.

The temperature was 104.8°F by rectum, the pulse rate 110, and the respiratory rate 24. The blood pressure was 100/50.

Examination of the blood revealed a red-cell count of 4,350,000, with 14.0 gm of hemoglobin, and a white-cell count of 16,800, with 88 per cent neutrophils, 10 per cent lymphocytes and 2 per cent monocytes. The sedimentation rate was 14 mm in 1 hour (Wintrobe method). The urinary sediment contained 5 to 10 red cells and 2 to 4 white cells per high-power field; subsequent urinalyses were negative. Each of two blood cultures revealed the presence of a Type VIII pneumococcus, which was sensitive to 0.02 units of penicillin per cubic centimeter. A serologic test for syphilis was negative. Roentgenographic examination of the chest, paranasal sinuses and skull was negative, and an electrocardiogram was interpreted to be within normal limits.

Lumbar puncture revealed an initial spinal-fluid pressure equivalent to 260 mm of water. Approximately 15 cc of turbid fluid was removed, and 20,000 units of penicillin was instilled intrathecally. Examination of the spinal fluid disclosed 264 white cells per cubic millimeter, with 86 per cent neutrophils and 14 per cent lymphocytes, a sugar of 65 mg, a protein of 45 mg per 100 cc and a chloride of 671 mg per 100 cc. No organisms were found on direct smear or on culture. The patient was given 100,000 units of penicillin intramuscularly every 2 hours, and 24 hours later the temperature had dropped to 97.8°F, remaining within normal

limits except for elevations to 100°F on the 2nd and 3rd days of therapy. The headache and stiff neck subsided on the 2nd day, the patient's appetite improved, and by the 4th day he was completely asymptomatic and ambulant.

A second lumbar puncture on the day after admission again disclosed an initial spinal-fluid pressure equivalent to 260 mm of water. The cerebrospinal fluid contained 46 white cells per cubic millimeter, with 72 per cent neutrophils and 28 per cent lymphocytes. Penicillin, 20,000 units, was instilled intrathecally and on the 2nd hospital day the spinal fluid pressures were normal and the fluid clear.

Penicillin was discontinued on August 4 after a total of 10,470,000 units had been given. Five blood cultures taken during the period of treatment and five taken at daily intervals after cessation of penicillin therapy showed no growth. The apical systolic cardiac murmur became less harsh and at times assumed a high-pitched quality. The spleen was no longer palpable on the 23rd hospital day.

Because of his apparent recovery, the patient was allowed to go on leave on August 13. During the trip home he experienced vague, intermittent pains in the right lower abdomen, lasting 12 hours. On the morning of August 15 he felt a sudden, sharp pain in the left axilla, with increasing discomfort during the day. He was seen by his physician at home, the left upper extremity was placed in a sling, and he returned to this hospital on August 16.

The apical murmur had not changed, the spleen was not palpable, and the only new physical findings were confined to the left upper extremity. There was extreme tenderness in the left axilla, with swelling, marked induration and increased warmth in the region of the first portion of the brachial artery about 5 cm distal to the apex of the axilla. Pulsations were palpable proximal but not distal to that site, but the radial pulse was palpable, though markedly reduced on that side. The entire extremity, however, was warm, and there were no color changes. Mild edema was present in the forearm and hand. The blood pressure was unobtainable on that side.

The temperature was 99.6°F by mouth, the pulse 100, and the respirations 20.

Examination of the blood disclosed a white-cell count of 13,800, with 62 per cent neutrophils, 36 per cent lymphocytes and 2 per cent monocytes. The sedimentation rate was 44 mm in 1 hour (Wintrobe method). The urinary sediment contained 5 or 6 red cells and 4 or 5 white cells per high-power field, but subsequent urinalyses revealed a normal sediment. Four blood cultures were sterile.

The diagnosis of brachial-artery occlusion was made, and the patient was given an initial dose of 300 mg of dicumarol, 50 mg of heparin intravenously every 4 hours and 200 mg of papaverine every 2 hours. A left stellate ganglion block was followed by some increase in warmth of the extremity but no increase in the intensity of the radial pulse.

Dicumarol was continued in amounts that maintained the prothrombin time between 19 and 29 per cent. Oscillometric determinations revealed markedly reduced pulsations in the first portion of the brachial artery and only slight oscillations below that point. The induration and tenderness at the site of thrombosis subsided within 3 days, after which the patient was allowed out of bed. An electrocardiogram on August 17 again revealed a normal tracing, and radiographic examination of the heart, including a barium swallow, revealed no abnormalities.

On September 4 a fusiform enlargement was noted for the first time slightly above the previous site of occlusion, and the oscillometric readings over this area were increased. On the following day, the patient complained of transient numbness and coolness of the hand, but no color change or diminution of the peripheral pulses was detected. In the next 3 days there were several transitory episodes of numbness unrelieved by a stellate ganglion block. On September 9 examination revealed an increase in the size of the pulsating mass, which measured about 5.0 by 2.0 cm. Rolling the mass under the fingers produced mild distal tingling (Tinel's sign), which was referred to the flexor surface of the thumb and index finger of the left hand. There was definite weakness of all the muscles supplied by the median nerve, and patchy hypesthesia to light touch and paresthesia to pinprick over the median sensory area. The diagnosis of brachial-artery aneurysm, with compression of the median nerve, was made, and the patient prepared for operation. He was given 60 mg of vitamin K intramuscularly every 3 hours during the night

and a transfusion of 500 cc. of whole, fresh blood. Prior to operation the next morning, the prothrombin time was 61 per cent.

On September 10 an incision was made over the first portion of the brachial artery. The median nerve was found lying in a groove in the aneurysmal sac. The median and ulnar nerves were dissected from the sac. The aneurysm was approximately 4 cm. in diameter, moderately thin walled and noncompressible. The proximal artery was patent and was occluded with a bulldog arterial clamp for 20 minutes during which the hand remained warm. The artery was then ligated proximally and distally and the sac with its vasa comitantes was removed. The distal artery was narrower than normal and contained a thrombus.

Gross tissue examination revealed a specimen consisting of a 37-cm. segment of brachial artery and vein, together with a small amount of perivascular tissue. Beginning 0.8 cm. below the proximal resected end and extending for a distance of 1.5 cm., the artery was dilated to a diameter of 3.2 cm. The vessel wall proximal to the aneurysmal dilatation was elastic, of normal thickness and lined by yellow smooth glistening intima. A branch artery arose from this portion. A groove previously occupied by the median nerve ran longitudinally along one side of the aneurysm which was filled with friable red thrombus. Its wall was thin, devoid of intima and hemorrhagic. Distal to the aneurysm, the artery was filled with a firmly fixed gray red thrombus which protruded from the resected end.

Microscopical examination of a section taken from the distal segment showed the lumen to be almost completely filled with an organizing thrombus containing well preserved red and white cells. The intima was destroyed at its point of attachment. In other areas the internal elastic membrane was broken up or absent. Numerous lymphocytes and a few polymorphonuclear leukocytes were present in the media, especially around the vasa vasorum. A few red cells were scattered between the muscle fibers. The mural architecture was completely destroyed and replaced by chronic inflammatory tissue in which fibrous tissue and lymphocytes predominated. Also present were neutrophilic and eosinophilic polymorphonuclear leukocytes, numerous macrophages filled with hemosiderin granules, areas of hemorrhage and small foci of necrosis. Cultures from the aneurysm and from the thrombus were sterile. The pathological diagnosis was chronic mycotic aneurysm of the brachial artery, with organizing thrombus.

The patient made an uneventful recovery and was discharged on the 15th postoperative day. He was seen 8 weeks after operation, when his only complaint was slight weakness and numbness of the left hand. Physical examination revealed that the apical systolic murmur had decreased in intensity, that no early or late diastolic, basal or apical murmurs had developed and that the median nerve function had improved. The left radial pulse was still absent, but no color or temperature changes were noted in the hand. The clubbing of the fingers and cyanosis of the nails were no longer present. A blood culture taken at that time was sterile.

#### DISCUSSION

Since the over-all mortality rate in bacterial endocarditis has been reduced to between 20 and

30 per cent by the use of antibiotics,<sup>2</sup> and the life expectancy of these patients prolonged, more active measures should be instituted in the treatment of mycotic aneurysms complicating the disease. Although these lesions may develop originally as a result of bacterial invasion of the artery, they should be sterile if the blood stream has been effectively cleared of organisms prior to surgery. Paul, Bland and White<sup>3</sup> and Klein and Crowell<sup>4</sup> reported sterile mycotic aneurysms in patients after treatment with penicillin. The case presented above demonstrates another in which a mycotic aneurysm was found to be sterile after control of the bacteremia by the use of penicillin.

Early surgical extirpation of these lesions should be performed whenever possible because aneurysms of this type are prone either to rupture or to impinge upon adjacent important structures. These complications may be avoided if the clinician is alert to the possibility of their development and institutes proper therapeutic measures before irreversible changes have occurred.

#### SUMMARY

A case of endocarditis due to a Type VIII pneumococcus, with recovery after treatment with penicillin, is reported.

The disease was complicated by the development of a mycotic aneurysm in the first portion of the left brachial artery, with compression and partial paralysis of the median nerve. Surgical removal of the aneurysm, which was found to be sterile at the time of operation, was followed by progressive improvement in the median-nerve function.

Whenever feasible, early surgical excision of an aneurysm of this type is recommended.

## PRIMARY HEMANGIOENDOTHELIOMA OF THE LIVER IN INFANCY\*

## Report of a Case

S W BEREZIN, M D,† J G SHARNOFF, M D,‡ AND J D STEIN, M D§

NEW YORK CITY

PRIMARY hemangioendothelioma of the liver in infancy is a rare disease as indicated by a review of the literature. In 1933 Kunstadter<sup>1</sup> reported 14 cases, reviewing 13 cases collected from the literature and adding 1 that had come under his observation. Since then Schumann,<sup>2</sup> in 1941, reported 2 additional cases, the first in a six-week-old infant and the second in a thirty-six-hour-old male infant who died of cerebral hemorrhage after delivery. Blauel<sup>3</sup> added 3 cases to the literature — 1 in an infant and 2 in children.

Foote<sup>4</sup> believed that these tumors were peculiar only to infancy. However, they may occur at any age. The patient in the case reported below is the youngest yet observed. The infant at the time of death was nine days old. The next youngest case is recorded by Bondy,<sup>5</sup> in which the patient was three weeks old at the time of death. The oldest recorded case was observed by Miller<sup>6</sup> in a man of seventy-six years.

These tumors are definitely of a malignant character, and are not to be confused with benign hemangiomas of the liver. They have been variously recorded in the literature as angiosarcomas, hemangiosarcomas, endothelioblastoma and so forth. The pathology has been thoroughly described.<sup>1, 4, 6</sup> Grossly, the liver is enlarged, studded with numerous nodules varying in size from a millet seed to masses several centimeters in diameter. These nodules and masses can be seen on the liver surface and within its parenchyma. They present on cut section a dark-red center and an irregular yellowish-gray outer zone. Histologically, these masses consist of blood spaces lined by proliferating endothelial cells in single and multiple layers. In some areas the endothelial cells form papillary ingrowths or proliferate in compact masses.

As further evidence of the malignant character of the tumor, metastases have been observed in a number of cases. Kunstadter<sup>1</sup> reported that metastases were present in 33 per cent of the 14 cases recorded in his paper. Metastases have been observed in the retroperitoneal lymph nodes, vertebrae, skin, ribs, lungs, adrenal glands and spleen. Metastases are more commonly seen in adult cases and more rarely observed in infants, as in the case reported below.

The clinical manifestations are characteristic. There is usually a history of a large abdomen at birth or subsequent rapid abdominal enlargement. Constipation, abnormal stools, vomiting and progressive weight loss are the most frequently observed symptoms. In older patients pain is a common complaint. Pain is most often present in the lumbar, flank or shoulder area.

The physical examination discloses one constant finding. It is the observation of a large abdomen becoming rapidly larger. The enlarged abdomen is usually interpreted as caused by hepatomegaly or right-upper-quadrant masses. Jaundice and ascites are rarely observed.

The course in the disease is rapidly downhill. With the increasing enlargement of the liver, death soon follows. In the majority of the cases reported in infancy the patients died before six months of age. Death is interpreted as due chiefly to liver destruction by the neoplasm, or hastened by any metastases that may be present.

The diagnosis has never been made clinically. Usually the diagnosis becomes apparent after laparotomy or upon post-mortem examination.

## CASE REPORT

J M, a white female infant, was born in the hospital on March 3, 1945, after a normal, spontaneous delivery, with a birth weight of 7 pounds, 9 ounces. Except for several raised moderately large purple masses in the skin of the right shoulder, right ear lobe and both lower extremities, she appeared to be of normal development. The skin masses were considered to be simple hemangiomas.

The mother's past history was noncontributory, except that she was classified as an arrested case of pulmonary tuberculosis.

After delivery the patient did well until the 4th day of life when slight icterus was first noted. On the next day the abdomen became distended. Enemas failed to relieve the distention. On the 7th day of life the enlarged abdomen was flat to percussion, and the superficial abdominal skin veins were distended. It was believed that the abdomen was not tender to palpation and that the liver and spleen were not palpable. At that time the hemoglobin was 72 per cent (Sahli), with no erythroblasts seen in the peripheral blood smear. X-ray examination, consisting of a plain film of the abdomen, revealed a diffuse haziness suggestive of intra-abdominal fluid. The loops of small bowel seemed displaced to the left lower quadrant of the abdomen. An attempt at left paracentesis elicited a negative result, 5 cc of frank blood was obtained upon right paracentesis.

On the eighth day of life the patient appeared acutely ill. The sclerae were definitely icteric. The abdomen was more markedly distended. A surgical consultation on the same day elicited the suggestion that the infant had a congenital liver anomaly, but that the patient's condition was too poor for surgical intervention. The patient died on the following day. The temperature was never elevated. The weight remained stationary.

\*From the Pediatric Service (Dr. Harry S. Altman, physician in-charge) and the Laboratories of Pathology, Lincoln Hospital, Bronx, New York.

†Chief of pediatrics, Ft. Hamilton Station Hospital.

‡Chief of pathology, Mt. Vernon Hospital, Mt. Vernon, New York. formerly, chief of pathology, Lincoln Hospital, Bronx, New York.

§Assistant resident in pediatrics, Lincoln Hospital, Bronx, New York.

Post mortem examination disclosed a well developed, markedly icteric white female infant. Several raised moderately large, purple masses were noted in the skin of the right shoulder, right ear lobe and both lower extremities. The abdomen was distended. The liver edge was palpable just above the right inguinal ligament.

The thymus was of normal size, configuration and location. The lungs were well aerated and of normal configuration. Two hemorrhagic nodules were noted in the left upper lobe.

The heart was enlarged but of normal configuration. When the abdomen was opened the liver was seen to occupy three fourths of the cavity. The liver weighed 420 gm and was of normal configuration. The capsule was smooth and glistening. On section the parenchyma presented a variegated coloring. Deep-purple soft areas were seen interspersed with yellowish-brown and deep gray zones (Fig. 1).

The spleen was moderately enlarged but otherwise normal. The pancreas, adrenal glands and genitourinary and gastrointestinal systems, as well as the brain and pituitary gland showed nothing remarkable.

Sections from the skin masses revealed many markedly distended capillary vessels in the dermis that were closely

FIGURE 1 Tumor Masses in the Liver as Seen on the Cut Surface

packed. There was a scant interstitial stroma. The capillary vessels contained few erythrocytes. The endothelial cells were large but of uniform appearance.

Irregularly outlined masses in the liver (Fig. 2) demonstrated areas of dilated vascular sinuses lined by large endothelial cells, in many of which papillary excrescences composed of massed endothelial cells were seen. In other areas the endothelial cells were present in solid sheets. The endothelial-cell nuclei varied in staining intensity; many were large and vesicular, and others were markedly hyperchromatic. The hepatic lobules revealed marked central necrosis.

Sections taken from the hemorrhagic nodules in the lungs showed intra alveolar hemorrhage.

The final diagnoses were primary hemangioendothelioma of liver and benign hemangiomas of skin.

## DISCUSSION

It is suggested that in cases of infants or young children with rapid abdominal enlargement attributable to hepatomegaly, with or without jaun-

FIGURE 2 Photomicrograph of the Hepatic Neoplasm ( $\times 125$ )

dice, hemangioendothelioma of the liver should be considered as a possible diagnosis.

## SUMMARY

A case of congenital primary hemangioendothelioma of the liver in a nine-day-old infant is reported.

This is the youngest patient with such a disease yet observed.

The clinical and pathological aspects of the disease are reviewed.

## MEDICAL PROGRESS

### INTERCAPILLARY GLOMERULOSCLEROSIS (Concluded)

PAUL KIMMELSTIEL, M D,\* AND WILLIAM B PORTER, M D†

CHARLOTTE, NORTH CAROLINA, AND RICHMOND, VIRGINIA

#### RELATION TO HYPERTENSION AND ARTERIOLO-SCLEROSIS

A close relation between intercapillary glomerulosclerosis and arteriosclerosis of the kidney has been obvious to all observers<sup>4, 5, 7, 8</sup>. The two lesions roughly parallel each other, but a sufficient number of exceptions exist to justify the statement that the relation is likely to be coincidental. Although arteriosclerosis cannot be excluded as a contributing factor in bringing about intercapillary glomerulosclerosis, it cannot be regarded as the sole cause. In the age group in which most cases of intercapillary glomerulosclerosis occur, a large percentage of patients reveal marked arteriosclerosis of kidneys with or without the glomerular lesions. Intercapillary glomerulosclerosis has been observed occasionally without significant vascular changes<sup>4, 16</sup>.

The involvement of efferent arterioles in the process of hyalineization seems to be significant.<sup>7, 8</sup> Allen<sup>8</sup> emphasizes the fact that in his experience arteriosclerosis of efferent vessels is absent in nondiabetic cases. Confirmation of this observation on other large series of cases would indeed be desirable. If involvement of the efferent arterioles could be regarded as a specific change in intercapillary glomerulosclerosis, a new avenue of approach would be opened for an explanation of the peculiar glomerular lesion and its clinical counterpart. At present, however, factual observations in this respect are not substantiated in sufficiently large numbers to serve as a basis for a theory of the pathogenesis of intercapillary glomerulosclerosis.

Hypertension, if it occurs in intercapillary glomerulosclerosis, is more likely to be correlated with the accompanying arteriosclerosis. However, hypertension is not observed so constantly as arteriosclerosis in cases of intercapillary glomerulosclerosis. Most of the earlier reports<sup>20-24</sup> show benign and more often moderate arterial hypertension in practically all cases. Cases of malignant hypertension have not come to our attention. Later statistics, however, reveal a considerable number of cases of intercapillary glomerulosclerosis in which hypertension is absent. Laipply<sup>4</sup> found it in only 64.6 per cent, Henderson et al<sup>16</sup> in 60 per cent, and Goodof<sup>3</sup> in only 50 per cent. The low incidence of hypertension cannot fully be explained by the assumption that milder

or diffuse glomerular lesions were included in the statistics since the criteria given in some of them are undoubtedly those of intercapillary glomerulosclerosis of the nodular type. It must thus be concluded that hypertension, though present in a large percentage of cases of intercapillary glomerulosclerosis, — according to Henderson et al<sup>16</sup> twice as frequently as in diabetes without intercapillary glomerulosclerosis, — is not an essential part of the clinical syndrome and is present less frequently than arteriosclerosis.

In summary, arteriosclerosis roughly parallels the severity of intercapillary glomerulosclerosis, but the relation is likely to be coincidental. Involvement of the efferent arteriole is reported to be confined to cases of diabetes. Hypertension most probably related to the vascular rather than the glomerular changes occurs in about 58 per cent of the cases of intercapillary glomerulosclerosis.

#### RELATION TO RENAL IMPAIRMENT, UREMIA AND ANEMIA

Although renal function is markedly impaired in a large percentage of cases, death is just as often due to cardiovascular disease and intercurrent infections. Data concerning the renal function in this condition are still not so complete as may be desired. At least two thirds of the cases show evidence of renal insufficiency as indicated by significantly elevated urea nitrogen or nonprotein nitrogen. Anson<sup>22</sup> reports renal impairment in 66 per cent, Henderson et al<sup>16</sup> in 64 per cent, Porter and Walker<sup>21</sup> in 60 per cent, Siegal and Allen<sup>6</sup> in 80 per cent, and Newburger and Peters<sup>20</sup> in 75 per cent. Death in uremia is reported to have occurred in 17.7 per cent by Laipply<sup>4</sup> and in 33 per cent of 12 cases reported by Chasnoff<sup>23</sup>. The hypochromic microcytic anemia seems to be roughly parallel to the impairment of renal function<sup>10</sup>.

In the remaining cases cerebral accident, cardiac failure, coronary occlusion and other manifestations of cardiovascular lesions are responsible for death. Incidental causes of death are likewise reported in a relatively small percentage<sup>16</sup>. No definite statement can be made regarding the prognosis. Only Spühler<sup>11, 12</sup> and Auroi<sup>10</sup> venture to predict that death may be expected two or three years after the syndrome has fully developed.

In summary, rather scant data concerning the involvement of renal function show impaired function in approximately 68 per cent and uremia in about 25 per cent of patients with intercapillary

\*Pathologist, Charlotte Memorial Hospital, Charlotte, North Carolina.  
†Professor of medicine, Medical College of Virginia, Richmond, Virginia.

glomerulosclerosis not dying from nonrenal causes. Microcytic, hypochromic anemia seems to parallel renal impairment. According to some authors, death is expected two or three years after the clinical syndrome has fully developed.

#### DIABETES AND INVOLVEMENT OF ISLANDS OF LANGERHANS

Most patients suffered from diabetes of relatively mild degree — as can be expected in the age group from fifty to seventy years in which the majority of these cases occur. It seems to be the rare exception that symptoms and signs of renal involvement antecede detectable diabetes by a few months.<sup>1</sup> Auroi<sup>16</sup> remarks that one should examine for "masked" diabetes in the presence of hypertension and the nephrotic syndrome. Almost always diabetes is recognized prior to the renal disease.<sup>17, 24</sup> In fact, the severity of intercapillary glomerulosclerosis seems to increase with the known duration of diabetes. Goodof<sup>2</sup> reported a consistent increase in severity after a known duration of six years, a statement fully confirmed by Henderson et al.<sup>18</sup> These observations appear to be adequate proof that the glomerular lesions are directly related to diabetes mellitus, though additional factors may be required for its precipitation. The severity of the diabetes, on the other hand, was not found to be parallel to the severity of the glomerular lesion,<sup>18</sup> nor did the treatment for diabetes seem to have any bearing on the renal involvement.<sup>18, 25</sup> It is for this reason that Dolger<sup>26</sup> has justifiably criticized the term "complication" as applying to vascular or glomerular lesions in diabetes. Since even the control of diabetes over a period of years cannot prevent the development of vascular and glomerular lesions, these should be considered as manifestations of the same basic disorder rather than "complications" of diabetes.

There is no direct relation between intercapillary glomerulosclerosis and hyalinization of the islands of Langerhans.<sup>2, 6, 18, 17</sup> Henderson et al.<sup>18</sup> conclude from their data that intercapillary glomerulosclerosis is not a more reliable criterion for post-mortem diagnosis of diabetes than the hyalinization of the island of Langerhans, in contrast to Lippay,<sup>4</sup> who considers intercapillary glomerulosclerosis the more reliable criterion.

Thus, in the great majority of cases, diabetes antecedes intercapillary glomerulosclerosis. The latter increases in severity after a known duration of diabetes of six years. Treatment for diabetes has no bearing on the development of intercapillary glomerulosclerosis. There is no consistent relation between intercapillary glomerulosclerosis and hyalinization of the islands of Langerhans.

#### RELATION TO RETINOPATHY

Retinal changes have frequently been mentioned in reports of cases of intercapillary glomerulo-

sclerosis, but only during the past year has the relation between retinopathy and intercapillary glomerulosclerosis been made the subject of specific studies. Henderson and his associates<sup>17</sup> found that retinopathy was present in 68.8 per cent of cases of diabetic intercapillary glomerulosclerosis, in contrast to 22.8 per cent of cases of diabetes without intercapillary glomerulosclerosis. Further analysis revealed two points of significance. In the first place, the great majority of cases showed a more complex type of retinopathy, the purely hypertensive type was present in only 1 out of 32 cases. Hence, retinopathy associated with intercapillary glomerulosclerosis almost always includes changes attributable to diabetes.

Secondly, in the subdivision and grading of the retinal changes, it was noted that the incidence of more complex and advanced types was higher in cases of diabetes with intercapillary glomerulosclerosis — those showing hemorrhages only or hemorrhages with punctate exudates were less frequently associated with intercapillary glomerulosclerosis. The authors concluded that the advanced type of diabetic retinopathy is more or less regularly associated with intercapillary glomerulosclerosis.

Dolger,<sup>1</sup> who based his report on a purely clinical study of a large number of patients, including 55 cases of juvenile diabetes, found that 50 per cent of his patients exhibited hypertension and albuminuria at the time of earliest retinal hemorrhages. His investigation correlates retinopathy with the clinical syndrome of diabetes, hypertension and albuminuria, assuming the identity of this syndrome with intercapillary glomerulosclerosis. This identity, however, is still being discussed. His statistics show the remarkable fact that there is practically no difference in the onset of retinopathy in the third and fourth decades of life, appearing thirteen years after onset of diabetes in each group of patients and being associated in 50 per cent with hypertension and albuminuria regardless of the age group. In patients of the fifth decade evidence of "accelerated vascular degeneration" with "earlier appearance of all abnormal findings" occurs at an average of ten years after onset of diabetes.

His observations show that retinopathy presages the vascular lesions and also, by implication, intercapillary glomerulosclerosis.

In summary, advanced retinopathy, specifically of the diabetic type, is more or less regularly associated with intercapillary glomerulosclerosis and should therefore be added to the complex clinical syndrome associated with the glomerular lesion. It precedes the renal changes and is more closely related to the diabetes than to the vascular or glomerular disease.

#### HISTOGENESIS

A number of notable contributions to morphologic details have been published in the litera-

ture,<sup>7, 9, 26, 27</sup> but this report concerns only studies that are pertinent to the problem of histogenesis.

The hyaline deposits in the glomeruli in hematoxylin-stained and eosin-stained sections often resemble amyloid, but do not possess its staining characteristics. Some authors believe it to be amyloid-like<sup>28, 29</sup>. Occasionally, it stains with Congo red, but Fahr,<sup>9</sup> who erroneously classified some of his earlier cases originally as amyloidosis, admits the lack of specificity of this staining reaction, and he, like most authors, concludes that the material cannot be identified as amyloid.

The glomerular changes, though often not in direct continuity with the hyalin in arterioles, were most commonly seen in senile kidneys and therefore originally conceived as aging or "axial" degeneration. In only two conditions, however, was this process observed in an extremely striking degree—namely, in diabetes and chronic intracapillary glomerulonephritis. Almost all subsequent observers have agreed with the descriptive identification of the lesion. Many have accepted the concept of intercapillary glomerulosclerosis, but some authors, notably Allen,<sup>8</sup> Laipply<sup>4</sup> and Bell<sup>7</sup> have disagreed with the assumption that the changes take place primarily in the intercapillary connective tissue. They have come to the conclusion that the lesions are produced by a splitting of the capillary basement membrane. Both Allen<sup>8</sup> and Bell<sup>7</sup> agree in their most important argument—that splitting and fraying of the inner basement membrane can be observed in early lesions.

In an analysis of the early lesion<sup>1</sup> it was found very difficult to determine accurately the origin of frayed fibers "splitting off" or "merging with" the capillary basement membrane. A special stain was devised for this purpose,<sup>2</sup> but the authors were finally convinced that conclusions regarding the origin of these fibers had to be reached by inference rather than by indisputable observation. All observers agree that the first appearance of fibers and hyalin occurs at the "inner" basement membrane—that is, the segment of the capillary wall that is situated toward the center of the lobule. To explain this position, which is characteristic for the early lesion, as well as its mode of extension, it was assumed that the original changes take place in the intercapillary connective tissue, the only available anatomic structure that could account for the peculiar topographic distribution.

To illustrate the complexity of this problem we refer to a recent study of the glomerular basement membrane by McManus.<sup>30</sup> His periodic acid stain reveals that the basement membrane of the arterioles is lost as the capillaries of the tuft form in the glomerulus. The basement membrane of capillaries appears to derive from Bowman's capsule, leaving points of reflection or the intercapillary space. This space usually appears empty, but very rarely contains cells of the "mesangium." In glo-

merulosclerosis, glomerulonephritis and eclampsia the space shows up better than it is usually seen.

Bell<sup>7</sup> does not accept the existence of intercapillary connective tissue in the periphery of the glomerular lobule. Zimmermann,<sup>31</sup> however, has convincingly demonstrated its occurrence in the normal glomerulus. The connective tissue is thickest at the pole, thinning gradually toward the periphery. We do not believe that it is possible to determine in any given section just how far out into the lobule it extends. Allen<sup>8</sup> speaks of a "mantle" surrounding the capillary loop corresponding to the adventitia. This tissue may be indistinguishable from the basement membrane and may, according to Allen,<sup>8</sup> take part in the process of hyalinization, although the lesion primarily involves the basement membrane.

Fahr<sup>9</sup> has recently proposed a new hypothesis concerning the histogenesis of intercapillary glomerulosclerosis. He compares the histologic structure of the glomerulus with that of the tubules. The latter are composed of epithelium, tunica propria and interstitial tissue, separating the tubules from the adjacent capillary membrane and its endothelium. He conceives of the glomerular tuft as a structure in which the tunica propria, the interstitial tissue and the capillary membrane have merged into one membrane. He therefore concludes that two forms of glomerulosclerosis can be distinguished—the capillary form, generally identical with arteriolosclerosis, and the extracapillary form, genetically analogous to hyalinization of the tunica propria of the tubules. It is the latter form that is identical with the lesion under consideration.

The terms extracapillary glomerulosclerosis (Fahr<sup>9</sup>) and mural glomerulosclerosis (Allen<sup>8</sup>) represent difference in interpretation, not in observation. We prefer to maintain the original term because it appears to be the most descriptive one, and because most authors agree that the fully developed lesion creates the impression that it is situated between the capillaries.

In summary, the concept that the glomerular changes originate from intercapillary connective tissue is reached by inference, mainly on the basis of its peculiar topography. There is, however, no unanimity of opinion in this respect. Various theories have been proposed. It is suggested that the term intercapillary glomerulosclerosis be retained since it has served well for the purpose of descriptive identification.

#### INTERCAPILLARY GLOMERULOSCLEROSIS AS A CLINICOPATHOLOGICAL ENTITY

The histologic segregation of the first 8 cases<sup>1</sup> seemed to be justified in part by the fact that certain clinical features were associated with the disease. It was then stated that a previous history of diabetes, edema of the nephrotic type and gross albuminuria were characteristic. Hypertension was

frequently present in cases associated with renal decompensation. Twelve years later Bell<sup>1</sup> concluded that clinical symptoms and signs of diabetes seldom warrant the diagnosis of intercapillary glomerulosclerosis. There are no definite clinical features, he states, by which diabetes with intercapillary glomerulosclerosis can be distinguished from diabetes without intercapillary glomerulosclerosis. A survey of the literature has shown that neither of the statements is entirely correct.

The accumulated experience since the first publication has shown that the complete clinical syndrome occurs in a relatively small percentage of cases of intercapillary glomerulosclerosis. With the exception of chronic glomerulonephritis, it can be stated that diabetes occurs in almost all cases of intercapillary glomerulosclerosis. Hypertension is found in approximately 60 per cent. Significant albuminuria is found in the majority of cases (approximately two thirds), edema of the nephrotic type in less than 10 per cent, impairment of renal function in from 50 to 75 per cent, uremia in roughly 20 per cent, and retinopathy in 86 per cent of cases with the advanced lesion. It is therefore correct to state that there are no definite clinical features to establish the diagnosis of intercapillary glomerulosclerosis. They are certainly not so definite as the histologic findings. Intercapillary glomerulosclerosis shares this fate with many other distinct pathologic conditions of inner organs.

Before final judgment is cast, two factors should be evaluated in future studies. The first is that a complete clinical investigation should be correlated to histologic findings, with specific reference to the degree and type of the lesion. Many of the older reports are not entirely conclusive in this respect. From some of the recent studies it seems likely that the severe, nodular type shows a closer and more consistent relation to the clinical symptomatology than the mild or diffuse type. Mild glomerular lesions are less apt to give rise to any component of the complex clinical manifestations, whereas the more severe lesions manifest themselves more completely.

Secondly, it is conceivable that the preponderance of the various components depends significantly on the age distribution. Spühler<sup>11, 12</sup> has suggested dividing the clinical picture into three types: diabetes in youth, beginning with nephrosis and later showing elevation of blood pressure and symptoms and signs of nephrosclerosis, diabetes in middle age, in which vascular and nephrotic syndromes develop simultaneously, and diabetes in old age, in which nephrosclerosis is predominant, often without the nephrotic syndrome.

Spühler<sup>11, 12</sup> has gained this impression from observations of his own relatively small series of cases. Discrepancies concerning the frequency of certain components of the clinical symptomatology may be solved if Spühler's concept can be

larger series. Most previously reported statistics do not lend themselves adequately to a respective analysis.

The question whether or not intercapillary glomerulosclerosis constitutes a clinicopathological entity cannot be answered with finality. Even though relatively rare, exceptions have been observed cases in which diabetes was absent, although the renal lesions were fully developed. It is also undoubtedly true that identical lesions occur in glomerulonephritis without diabetes in a significant number of cases. A similar situation, however, exists in many other "diseases" in which a definite pattern of clinical signs and symptoms is correlated to distinct pathological findings, although the same histologic change may occur in a different set of circumstances and may result from different etiologic factors. Should we abolish the concept of malignant hypertension because the same histologic changes in arterioles occur in periarteritis nodosa and lupus erythematosus?

Whether we look upon intercapillary glomerulosclerosis as a clinical entity depends to some extent on the approach to this question. The clinician, observing a diabetic patient who develops gross albuminuria, nephrotic edema, hypertension, impairment of renal function and retinopathy has in the past regarded such a condition as coincidental or as a concurrence of two or three different diseases.<sup>6, 11, 12</sup> He is now in a position, however, to predict with reasonable certainty a pathologic lesion in the kidney that is directly related to the basic metabolic disorder, — the diabetes, — merely constituting a variant of its manifestation. Obviously, there can be no accurate correlation between the histopathological findings in the glomeruli and the clinical symptoms. This is due to the fact that there is no way of determining accurately how many glomeruli are involved or to what degree protein metabolism is compromised by protein loss on the one hand and disturbance of protein synthesis on the other. It is obvious that the latter factor is considerably disturbed in patients with glomerulonephritis with the nephrotic syndrome, and apparently the same statement applies to the condition under discussion. One can say, however, that in a patient fifty or more years of age with chronic diabetes, nephrotic edema and albumin in the urine with high blood cholesterol, one can safely make the diagnosis of intercapillary glomerulosclerosis with approximately 100 per cent accuracy. Glomerulonephritis is rarely a problem in patients of this age group. Repeated Addis counts noting the number of red cells and casts excreted each twenty-four hours will certainly enable one to make the diagnosis of glomerulonephritis, for in that condition red cells will appear in pathologic numbers in contrast to lack of hematuria of significant degree in intercapillary glomerulosclerosis.

The diagnosis of this disorder carries with it a grave prognosis, which cannot be influenced by treatment of diabetes. It is true that the clinical diagnosis of intercapillary glomerulosclerosis is not infallible, but the "presence of advanced lesion can be predicted with considerable certainty."<sup>16</sup> It is inferred from the study of the literature that most authors have shared this experience. The difficulty in recognizing earlier or less advanced lesions does not interfere with the concept of intercapillary glomerulosclerosis as a clinicopathological entity. It should rather constitute a challenge to a search for better criteria for early diagnosis.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

### Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

BENJAMIN CASTLEMAN, M.D., *Associate Editor*

EDITH E. PARRIS, *Assistant Editor*

### CASE 34261

#### PRESENTATION OF CASE

*First admission.* A thirty-year-old Negro entered the hospital because of weight loss and flank pain.

Six weeks before admission the patient developed a urethral discharge three days after suitable exposure. This was diagnosed as gonorrhea by his physician, and treatment consisted of four injections of penicillin followed by three tablets of sulfadiazine every four hours for four days. He stopped "half-way through the treatment" because of malaise and feverishness. Two days after the sulfadiazine was stopped he became oliguric, and two days later anuric. The anuria lasted for two days and was succeeded by polyuria, nocturia, cloudy urine and flank pain. Over the next four weeks the last two symptoms gradually subsided but the polyuria, nocturia (three times) and general malaise continued and the patient lost 25 pounds. There was no dysuria, hematuria or colicky pain. Four days before admission he noted the onset of continual nausea, occasional vomiting, cramping of the fingers and blurring of vision.

Twelve years before admission the patient had contracted pulmonary tuberculosis and spent three years in a sanatorium.

Physical examination showed a well developed, thin, pale Negro. The left chest moved poorly with respiration, and there was decreased resonance, breath sounds and spoken voice over the left upper lobe. Bilateral costovertebral-angle tenderness was present.

The temperature, pulse and respirations were normal. The blood pressure was 100 systolic, 60 diastolic.

The hemoglobin was 12 gm per 100 cc, and the white-cell count was 7100. Urinalysis showed a specific gravity of 1.010, a ++ test for albumin, no red cells and 5 to 10 white cells per high-power field. A culture of the urine grew a nonhemolytic streptococcus and *Staphylococcus albus*. Repeated sputum examinations were negative for acid-fast bacilli. The nonprotein nitrogen was 100 mg, and the total protein 4.1 gm per 100 cc, with an albumin-globulin ratio of 0.9, the serum calcium was 7.7 mg and the phosphorus 4.6 mg per 100 cc, and the carbon dioxide was 19.3 milliequiv per liter. There was no sulfonamide in the blood. A phenolsulfonephthalein test showed less than 5 per cent excretion of the dye in two hours. A blood Hinton test was negative. The basal metabolic rate was -26 per cent. X-ray films of the chest showed findings consistent with an old pneumothorax on the left side and resulting pleural thickening. There was no evidence of activity. A plain film of the abdomen displayed no unusual features. The kidney shadows were incompletely visualized.

The patient improved somewhat on a low-sodium, normal-protein diet and forced fluids. The nonprotein nitrogen fell to 74 mg and the phosphorus to 4.6 mg per 100 cc.

The patient was discharged to be followed in the Out Patient Department

**Second admission** (two months later) He did well at home for several weeks but then noted the onset of malaise, intermittent ankle edema, nausea, occasional vomiting and a chronic cough productive of whitish sputum. Left costovertebral angle and flank pain persisted, as well as nocturia (two or three times). There were no chills, fever, dysuria or hematuria.

Physical examination showed, in addition to the findings on the first admission, generalized, firm, mobile, discrete, nontender lymphadenopathy and minimal pitting edema of the legs and ankles.

The hemoglobin was 8.5 gm, and the white-cell count 9600. Urinalysis showed a specific gravity of 1.012, a +++ test for albumin and numerous white cells. There was no growth on culture of the urine. The nonprotein nitrogen was 61 mg, the total protein 5.7 gm (albumin-globulin ratio of 0.8), the serum calcium 8.5 mg, and the phosphorus 4.5 mg per 100 cc. Two Congo-red tests showed respectively 41 per cent and 70 per cent retention of the dye in the serum. In an x-ray film of the chest no change was seen in the left lung, whereas in the right there was an area of increased density at the right base and a similar area previously noted at the right hilus was somewhat larger.

Very little change was noted in the patient's clinical condition or laboratory data during this hospital stay, and he was discharged on the seventeenth day.

**Final admission** (four months later) The patient did fairly well on bed rest at home for two months, but then coincident with his getting up he suffered a return of the old symptoms — malaise, anorexia, nausea, vomiting and pain in the left flank, radiating around to the groin. All these progressed and as the vomiting became worse the urine output decreased. During the week before admission he noted facial edema in the mornings and occasional twitching of the legs.

Physical examination showed a thin, moderately dehydrated, sleepy, yet well oriented man lying flat in bed. Aside from the patient's general condition the physical findings had not changed.

The temperature, pulse and respirations were normal. The blood pressure was 95 systolic, 60 diastolic.

The hemoglobin was 8 gm, and the white-cell count 13,300, with 92 per cent neutrophils. Urinalysis showed a specific gravity of 1.010, a +++ test for albumin and 1 or 2 red cells and 0 to 2 white cells per high-power field. Again, urine cultures grew nothing. The nonprotein nitrogen was 176 mg, the total protein 4.0 gm (albumin-globulin ratio of 0.7), the serum calcium 5.3 mg, and the phosphorus 16.6 mg per 100 cc. The carbon dioxide was 24.9, the chloride 86, the sodium 125,

and the potassium 7.3 milliequiv per liter, and the cholesterol 208 mg per 100 cc. X-ray films of the chest and abdomen showed no essential change except for disappearance of the area of increased density at the right base.

The patient gradually lapsed into coma, the temperature became subnormal, reaching a low point of 93°F (rectal), the pulse remained in the neighborhood of 70 to 80, and the respirations varied between 12 and 20. Muscular twitching was prominent. He was given plasma, physiologic saline solution, sodium lactate and desoxycorticosterone acetate. In spite of this the serum sodium fell to 108, the carbon dioxide to 15.5, and the chloride to 57 milliequiv per liter. The nonprotein nitrogen rose to 240 mg per 100 cc. Terminally, respirations became slow and deep, the pulse was slow, and the blood pressure fell to 60 systolic, 20 diastolic. He died quietly on the fifteenth hospital day.

#### DIFFERENTIAL DIAGNOSIS

**DR. JACOB LERMAN:** Two Congo-red tests showed respectively 41 per cent and 70 per cent retention of dye in the serum.

That is an important statement. These tests were done in a short space of time. Therefore, I must accept the 41 per cent retention of the dye as more valid than the 70 per cent, because the previous uptake of Congo red by the liver cells would have given falsely high results in subsequent tests.

On the first admission we find that the patient reacted to sulfonamides, resulting in renal shutdown. Most likely this was due to the deposit of crystals in the tubules rather than to a sulfonamide type of acute nephritis. In the course of the following four weeks he began to develop evidence of marked renal failure. Because of the short duration one must assume that this man had underlying renal disease. Otherwise, it is hard to explain the rapid progression of renal failure. He began to show polyuria, nocturia, malaise, weight loss and so forth. He began to retain phosphorus and developed symptoms of tetany. The laboratory data subsequently verified this — that is, the blood calcium dropped. We also learn that he had had pulmonary tuberculosis in the past.

He showed, on examination, bilateral costovertebral angle tenderness, which we assume was due to infection in the kidneys. It might have been due to residue of crystals in the tubules, although that is not likely. It was about four weeks from the onset of the first damage by sulfonamides, and we would expect no more physical signs at that time. The urinary findings favor renal infection. In addition, he began to show evidence of acidosis. The reduced carbon dioxide was probably the result of damage to the ammonia-producing mechanism, so that he was losing a great deal of

base The basal metabolic rate was -26 per cent I assume that it was taken because someone suspected lipid nephrosis Actually, we do not have much evidence for lipid nephrosis here Later on, we learn that the cholesterol was normal On the second admission he developed a chronic cough and further changes in the lung seen on x-ray examination It might be well to look at the films

DR STANLEY M WYMAN The old thickened pleural line is seen overlying a partially collapsed left lung, and some calcification is seen in this area, probably lying posteriorly and not in the lung itself There are a few small mottled areas of calcification in the right upper-lung field The heart is drawn toward the left The left costophrenic angle is obliterated by the old pleuritis There is an indefinite shadow of density overlying the right hilus, which persists on the next examination and seems still larger about two months later At that time there is a small area of hazy density in the right costophrenic angle The last film of the chest shows a decrease in size of the round area of density over the right hilus The left chest shows no definite change at this time The two films of the abdomen outline very poorly the kidney shadows I think the right kidney may be a little large The left I cannot adequately see The liver does not appear enlarged, the spleen cannot be outlined

DR LERMAN Are there any renal calculi?

DR WYMAN No, I do not see any in these films I also do not see any unusual soft-tissue masses

DR LERMAN There is mention of a shadow at the right base, which decreased in size

DR WYMAN Yes, this is the one in the right lower-lung field that disappeared in four months The second shadow had become somewhat smaller

DR LERMAN On seeing the x-ray films, I wonder if one might conjure up such a diagnosis as cancer of the lung, particularly lymphoma The disappearance of this shadow and the changes in the mediastinum tend to rule out this diagnosis

On the final admission he developed dehydration and marked chemical changes in the blood, which I shall discuss in a minute

It seems to me, from the evidence available, that there was an underlying chronic pyelonephritis, resulting in renal failure In addition, the evidence seems to point toward amyloid disease, particularly the high uptake of Congo red He had a good background for amyloid disease—namely, long-standing pulmonary tuberculosis Unfortunately, we find no mention of the size of the liver or spleen, although Dr Wyman has just said that the liver was normal in size and that the spleen could not be visualized Is that correct?

DR WYMAN So far as I can see

DR LERMAN The evidence of tubular damage we have obtained from the history also favors amyloid nephrosis Mention is made of generalized lymphadenopathy in addition to the nodes in the

mediastinum The only conclusion that I can make is that this was not lymphoma, but rather tuberculous nodes In addition, he had evidence of clinical tetany With a low calcium and high phosphorus of this degree, we must assume that the pathologist will find secondary hyperplasia of the parathyroid glands

How can we explain the dramatic change in the blood chemical findings? I refer to the very low levels of blood sodium and chloride and the high blood potassium These raise the question of Addison's disease We have here a possible background for Addison's disease—namely, long-standing pulmonary tuberculosis Therefore, damage to the adrenal glands is possible There is no mention and we see no evidence of calcification of the adrenal glands Although this does not rule out Addison's disease, it certainly does not favor it The history in itself does not give clues to any previous episodes of adrenal failure This patient had plenty of opportunity to develop adrenal failure, particularly following the reaction to sulfonamides However, there is no evidence of adrenal failure at that time As I interpret the x-ray films he had a normal-sized heart Do you agree, Dr Wyman?

DR WYMAN Yes

DR LERMAN In general in Addison's disease one finds a rather small heart I think one can account for the marked changes in the blood chemical findings by the fact that the patient was severely dehydrated He had lost a good deal of sodium and chloride by vomiting and a good deal of base through the kidneys as a result of damage to the ammonia-producing mechanism Also, the failure of the blood to improve even transiently from treatment with salt and desoxycorticosterone acetate is against the diagnosis of adrenal failure

One thinks also of renal tuberculosis as a complicating factor here We have not enough evidence for it There was no significant hematuria, and nothing is mentioned in the examination of the urine to give a positive clue So I have to rule it out

DR F DENNETTE ADAMS How do you account for the pain? It worries me The patient came in complaining of pain

DR LERMAN I thought we might find evidence of renal calculus However, the absence of hematuria and these x-ray films make one believe that there is not enough evidence for renal calculus Perhaps the patient passed a stone He also complained of pain in the flank on the second admission It could be explained by pyelonephritis, since there is evidence of renal infection

DR ALFRED KRANES Do we know how long he had the low-sodium diet? Was he on it during the entire period?

DR ERNEST CRAIGE About four months

Dr. KRANES The reason I ask is that this type of death has been described in people with renal disease on a low-sodium diet and is something that should be borne in mind. The clinical findings of so-called sodium-depletion shock resemble acute renal insufficiency. In addition to the mechanism that Dr. Lerman mentioned, it may be partially responsible.

Dr. EDWARD F. BLAND He did not respond promptly to cessation of the low-sodium regime.

Dr. TRACY B. MALLORY On the last entry he received adequate saline solution.

Dr. LERMAN I had assumed that he was on the low-sodium diet only on the first admission, since subsequently the diet was not mentioned. I had supposed that later he was placed on a normal diet — apparently this is not so.

Dr. CRAIG He was carried at home on a moderately low-sodium diet. During the last admission he was given a great deal of salt and sodium lactate. He failed to improve, however.

The opinion on the ward on the first admission was that he had a sulfonamide nephrosis, but that diagnosis was dropped when he failed to recover after three weeks. Later on there was increasing evidence of chronic nephritis and on the last admission the diagnosis was chronic glomerulonephritis.

Dr. MALLORY On the first entry he was presented at Grand Rounds, and I saw him on that occasion. The service at that time seriously considered the possibility of a sulfonamide nephrosis. So far as I know, no such case has ever been seen to progress to a chronic renal lesion — the patients either recover or die in the acute stage. It became obvious as time passed that some other renal condition must have been present.

Dr. KRANES The other thing I have in mind is the question of amyloidosis. This patient had the setup for amyloidosis, with the long-standing tuberculosis, but I do not believe the evidence in the record justifies one in making that diagnosis. The retention of 41 or even 70 per cent, although it may indicate amyloidosis, does not necessarily do so. An interesting series of studies was carried on in New York on this problem, and not infrequently the retention was as high as 80 and 90 per cent, not followed necessarily by the finding pathologically of amyloid disease.

Dr. BLAND What were your final diagnoses, Dr. Lerman?

Dr. LERMAN Chronic pyelonephritis, amyloid disease, old pulmonary tuberculosis and tuberculous adenitis.

Dr. MALLORY Are you satisfied on the films that that is thickened pleura?

Dr. WYMAN The appearance has not changed since the first examination — over a period of seven months. It is probably thickened pleura in addition to old empyema and old fluid. One

cannot say roentgenologically whether it is solid tissue or encapsulated fluid. The hilar masses I cannot explain except to call them enlarged lymph nodes. I cannot exclude entirely a tumor at the hilus — actual new growth.

#### CLINICAL DIAGNOSIS

Chronic glomerulonephritis

#### Dr. LERMAN'S DIAGNOSES

Chronic pyelonephritis

Amyloid disease.

Chronic pulmonary tuberculosis

Tuberculous adenitis

Addison's disease?

#### ANATOMICAL DIAGNOSES

Pulmonary tuberculosis, chronic, inactive

Oligothorax

Amyloidosis of kidneys, spleen, and adrenal glands

Pulmonary edema, acute

Psoas abscess, tuberculous

#### PATHOLOGICAL DISCUSSION

Dr. MALLORY At autopsy the left lung was markedly compressed by a large, very thick-walled sac, and when we cut into it we found that the center consisted entirely of oil. Eventually, we were able to get a history from the tuberculosis sanatorium in which the patient had been that they had injected demerol in oil during his stay there, and the oil had evidently persisted ever since. There was at least 300 cc. The remainder of the cavity consisted of cheesy, necrotic material, completely unidentifiable under the microscope. We found in the lung a number of scattered calcified foci evidently representing healed tuberculosis, but no evidence of activity.

There was a psoas abscess. The liver was completely normal. The spleen was firm, quite pale and characteristic of amyloid. The kidneys were slightly enlarged, had smooth surfaces, were of waxy consistence and, again, were grossly consistent with amyloid. Nothing remarkable was noted about the adrenal glands on gross examination, except that they were heavy, weighing 26 gm. Microscopically, there was evidence that the adrenal substance was almost completely replaced by amyloid. So I think that the patient probably had Addison's disease, based not on tuberculosis but on the amyloid involvement of the adrenal glands. The lesion in the kidney likewise proved to be pure amyloid, with no evidence of nephritis.

CASE 34262

#### PRESENTATION OF CASE

A fifty-four-year-old man was admitted to the hospital with a mass over the right anterior chest.

Ten months before admission the patient experienced a sharp pain over the right anterior chest,

which he attributed to trauma. The pain soon disappeared, and he forgot all about it. Two months prior to admission, following a routine x-ray examination of the chest, a tumor involving the right fifth and sixth ribs was discovered. At that time the patient was in another hospital undergoing treatment for rheumatoid arthritis, involving the cervical spine, the knees and the right middle finger, of about five years' duration.

Physical examination revealed a well developed and well nourished man. Evidence of rheumatoid arthritis, without acute activity, was present in the cervical spine, the right knee and the right middle finger. A tender, questionably nodular mass was present over the right fifth and sixth ribs in the midclavicular line. Auscultation disclosed a Grade I systolic murmur at the base of the heart.

The temperature, pulse and respirations were normal. The blood pressure was 140 systolic, 90 diastolic.

Examination of the blood showed 13.2 gm of hemoglobin and a white-cell count of 8500, with 63 per cent neutrophils, 26 per cent lymphocytes, 7 per cent monocytes and 4 per cent eosinophils. The urine was normal. The sedimentation rate was 18 mm in 15, 42 mm in 30 and 52 mm in 45 minutes and 54 mm in 1 hour. X-ray examination revealed a destructive process involving the anterior axillary portion of the right sixth rib over a distance of approximately 7 cm. There appeared to be a soft-tissue mass surrounding this area. The trabeculae were increased in prominence, and the rib appeared expanded and destroyed. The extreme anterior tip of the rib was spared. No other definite lesions were seen in the remaining ribs, the thoracic or lumbar spine, pelvis, upper humeri or femoral shafts. There were degenerative changes about the lower thoracic and lumbar vertebrae and about the hip joints. There was some kyphosis of the upper thoracic spine. The left kidney was poorly visualized on the films of the spine, and appeared grossly normal, the right kidney was not adequately seen.

On the second hospital day an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR WILLIAM S. CLARK. It seems reasonable to accept the diagnosis of rheumatoid arthritis in this patient because of the fact that he had had symmetrical joints involved, and because the distribu-

tion of joint involvement is quite consistent with that diagnosis. It should be pointed out here that this man was apparently in good health at the time of admission. Even with rheumatoid arthritis he was in a good state of nourishment, and except for the rapid sedimentation rate he had very little evidence of constitutional disease.

To learn more about the rib lesion and also to find out what we can about the rheumatoid arthritis let us look at the x-ray films. First of all may we see the films that suggest the presence of arthritis, particularly those of the sacroiliac region?

DR JAMES J. MCCORT. There is no evidence of arthritis in the sacroiliac joints. I do not have the films of the other bones that showed the arthritis. These are the films that you have already seen, and the mass is apparent on the routine chest film extending into the pleura and on this other film one can see the mass extending outside the chest wall. There is definite destruction of the right sixth rib in the anterior axillary line. The rib is destroyed in that area. The lesion is more or less destructive, and there is no new bone formation, no spicule formation in the soft tissue and no periosteal reaction over the edges of the rib. The extreme anterior segment of the rib is intact. The soft-tissue tumor is smooth and shows no calcification within it.

DR CLARK. How about the trabeculae that are described in the protocol?

DR MCCORT. I would interpret it as meaning that the smaller trabeculae were destroyed so that the remaining trabeculae stood out, rather than thinning per se of the trabeculae.

DR CLARK. There were no trabeculae coursing through the tumor apparently. I think with the history of joint involvement that one might consider the possibility of some new bone formation and perhaps fuzziness along the margins of the sacroiliac joints. The evidence is certainly not striking, however.

DR MCCORT. We would like better films to determine that.

DR CLARK. First of all I do not believe we need consider this lesion of the rib as being one of the manifestations of rheumatoid arthritis. I know of no such destructive lesion of bone that occurs in the course of that disease, though we have to consider that (in the course of rheumatoid arthritis) he had developed an additional lesion of the rib. The first thing we should decide is whether this

was an inflammatory lesion or a tumor. There is very little in the protocol to help decide that. The patient was in apparent good health, the white-cell count showed no evidence of infection and there are no data to support the thesis that this might have been a granuloma. So I am going to discard that possibility, although the evidence against it is not too strong, and conclude that it was a tumor.

There are very few primary tumors so far as I know that involve the ribs. We will consider some of these, perhaps in an encyclopedic fashion, because I suppose any one of them could be the final diagnosis. Perhaps one of the more common rather benign tumors that involve the ribs is a chondroma. I suppose such a tumor could fit this picture, but the chondroma as I understand it is usually related to the small joints of the thoracic cage and since a portion of the rib adjacent to the costochondral junction is spared, I think we can discard that possibility. Giant-cell tumors of the rib are reported, and I inquired about the trabeculae because I thought this tumor might have had the appearance of a giant-cell tumor. In this age group I think that would be something to which one should give a little more than the usual amount of consideration, but we really have nothing to support it from the x-ray appearance and as I understand it the x-ray findings are reasonably characteristic in giant-cell tumors. A Ewing tumor is unlikely in a person of this age, particularly with the history of a relatively long pain-free period following the onset of the lesion. The pain in Ewing's tumor usually increases with time, and the tumor may also be accompanied by secondary constitutional manifestations not present here, particularly leukocytosis and fever. The other thing about Ewing's tumor that rules it out fairly well is the absence of new bone formation.

We have to consider the possibility of multiple myeloma although solitary lesions in myeloma are extremely rare. The x-ray films show no evidence of additional lesions. On the basis of the improbability of finding one solitary lesion representing myeloma we can discard that diagnosis. Another point against multiple myeloma is the fairly normal peripheral blood count. I think even if this were a solitary lesion of that nature there would also have been some infiltration of the bone marrow resulting in anemia. Hodgkin's granuloma also is seen under such circumstances, but I think rarely when it is the first manifestation of

disease. Again, the apparent well-being of the patient and the lack of abnormalities in the peripheral blood are against that diagnosis. I believe if there were such a lesion of bone whereby the disease would be noticed, there would also have been infiltration of the bone marrow. Incidentally, the eosinophil count of 4 per cent is quite consistent with rheumatoid arthritis—it is not really an abnormal finding. We really cannot find any good evidence to support any of these diagnoses. There is nothing in the protocol that indicates that this man had a tumor elsewhere and that this was a metastatic lesion. The fact remains that by far the most common tumors that occur under such circumstances are metastatic lesions.

It is true, again, that the patient was in apparent good health, and the thesis that he had a malignant tumor elsewhere metastasizing to the rib might not hold up. There is no evidence of involvement of systems other than what is noted about the kidneys—namely, that they were poorly visualized. I do not consider that of any value in making this type of decision, and the urine was normal. Purely on the basis of probability, as well as the fact that this was a destructive lesion, I prefer to consider a metastatic tumor of the rib. If I were looking for a primary site, I suppose it would be best to consider the thyroid gland or the stomach or the kidney. There is no evidence that he had carcinoma of the stomach, and again the anemia may be evidence against that diagnosis. The thyroid gland was not reported as abnormal. So I shall say that this was a metastatic tumor of the rib, possibly from a hypernephroma or renal-cell carcinoma.

#### CLINICAL DIAGNOSIS

Metastatic carcinoma of rib, of thyroid or renal origin

#### DR. CLARK'S DIAGNOSIS

Metastatic tumor of rib, possibly hypernephroma or renal-cell carcinoma

#### ANATOMICAL DIAGNOSIS

Metastatic renal adenocarcinoma

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: It was decided to examine the rib lesion. One of the problems we have

to face in the laboratory almost every day is that of attempting to give the clinician a lead where to seek the primary tumor from the microscopical appearance of metastasis. A large part of the time we are entirely unable to help him, but in this case, we were dealing with one of the histologically most characteristic neoplasms, a clear renal-cell carcinoma, and it was possible to make a flat-footed diagnosis from the biopsy of what is ordinarily called hypernephroma. The patient was then turned over to Dr Leadbetter.

DR WYLAND F LEADBETTER. On the basis of the biopsy report we assumed that the patient had a renal-cell carcinoma. A retrograde pyelogram showed characteristic changes in the calyces of the right kidney compatible with the diagnosis of renal-cell carcinoma. No other metastatic lesions were found, so we thought that it was worth while to remove the right kidney if the lesion was operable. Later on it was planned to remove the metastatic lesion in the ribs. That was done — a transperitoneal right nephrectomy. We were able to remove the kidney together with the fat and the fascia. We did not see the kidney at any time during the operation. The vessels were tied, and the kidney and enveloping fascia were shelled out en masse. The operation was satisfactory, and the patient made a good recovery. Dr Grantley W Taylor is now going to remove the metastatic lesion in the rib.

DR MALLORY. We have an occasional case in which very notable remissions have followed re-

moval of the kidney and a solitary metastasis. Dr Barney\* had one case that was quite dramatic.

DR J DELLINGER BARNEY. I had a case with Dr Donald King some years ago in which the patient was suspected of having tuberculosis of the lung. X-ray study showed a mass in the lung about the size of an English walnut, which we first thought might be a tuberculoma. Later, a tumor of the kidney was discovered and removed, and then we decided that the lesion in the lung was probably a metastasis. It grew slowly and was not affected by x-ray therapy. During a long period of observation no other metastases appeared. It was decided that this probably was the only metastatic lesion that the patient had. Dr Churchill was asked to see her with the idea of removing it. He thought it could be done and did it. That was fourteen or fifteen years ago. I have not seen her recently, but Dr King has and says that she is not only alive but also very well, with no evidence of metastases elsewhere.

DR MALLORY. Have you anything to add, Dr King?

DR DONALD S KING. We have not had as much good luck in removing apparently solitary metastases in the lung as we hoped we might have. Several patients have had metastases to the brain that did not become manifest until the supposed single metastasis to the lung had come out.

## —SUFFERETH LONG

THE time has come for a fresh appraisal of the various charitable undertakings of the country, at home and abroad, regarding both their needs and the means of supplying those needs. Scarcely a week now passes in which some special drive is not staged and a particular appeal presented, the demands are insatiable, the claims are constant, and some equitable method of assaying them and allocating to each its share of the available resources must be evolved.

In the Boston area a study is already on foot to analyze the expenditure in 1946 by tax-supported and voluntary agencies of \$88,000,000. This survey has received previous editorial comment in the *Journal*\*. More recently, at the joint annual meeting

of the Greater Boston Community Fund and the Greater Boston Community Council, the formation of a citizens committee to approve all the community's fund-raising appeals was recommended.

Already, and in steadily increasing numbers since the war ended, organizations are coming to the fore that make their independent solicitations for support, unrestricted by any acceptance of the quotas determined by the Community Fund. These appeals, on city, state and national levels, come from little known and scarcely recognized charities as well as from those country-wide associations, societies and foundations whose importance and whose authenticity are unquestioned. The success of their solicitations, however, is frequently based on their emotional appeal and perhaps sometimes on the extravagance of their suggestions rather than on the relative merits of the services they offer.

It will be readily admitted that the campaign for funds with which to study and treat infantile paralysis, as our most striking example makes a greater appeal and strikes more deeply into the pockets of the public than would any pleas for the where-withal with which to study arthritis, which cripples so many more victims. Many other of these independent organizations have also learned to dramatize their appeals in a way that does not always conform to even reasonable scientific accuracy. The American Cancer Society, for instance, when it states, in the course of its campaign for money, that 17,000,000 Americans will die of cancer "unless you do something about it" is presenting an unwarranted implication that enough American dollars can prevent all or most of the 17,000,000 deaths. Dollars are needed, true enough, but no guarantee of their purchasing power in terms of life should be implied. The public relations of the medical profession must be beyond reproach.

It seems apparent that the nation's money-raising enthusiasm should be tempered with sound judgment, that a fair appraisal of the merits of an appeal should be made and that money-raising activities should be conducted with the strictest candor and with a reasonable degree of co-ordination. The springs of private philanthropy may not run forever, but they will dry up less rapidly if their resources are pooled and properly dispensed.

\*Editorial: Greater Boston Community Service. *New Eng J Med* 238:340, 1948.

A local committee to approve publicly the fund-raising campaigns to be launched in a community will fill a needed want. A similar selective effort should be made regarding the larger organizations that operate on the grand scale. Our hearts go out to the citizens of Wichita, Kansas, referred to at the annual Community Fund and Community Council meeting, who conducted not long ago a "Leave Us Alone Week." It was the last bleat of the shorn lamb.

## BCG VACCINATION

THERE has been considerable discussion and interest in this country during the past two years in the use of BCG (*Bacillus Calmette Guérin*) vaccination as a means of immunization against tuberculosis. At a conference called in 1946 by the United States Public Health Service certain plans were formulated whereby a carefully controlled but well circumscribed study on a comparatively large scale could be carried out under the auspices of the Public Health Service. Because of growing interest in this subject, further seminars and conferences have been held in which the pros and cons of BCG vaccination were thrashed out by various experts in the field of tuberculosis. A summary of views of such experts was presented at a symposium sponsored recently by the National Tuberculosis Association.<sup>1</sup> Elsewhere in this issue of the *Journal* there is reprinted a statement of the present policy of the American Trudeau Society as submitted by the chairman of its chemotherapy committee and adopted by its executive committee. Finally, the views expressed at a conference called for that purpose in New York City last March were summarized by the chief of the Tuberculosis Control Division of the United States Public Health Service.<sup>2</sup>

It is clear from these reports and discussions that BCG vaccination is a safe procedure if used under proper supervision and in the proper circumstances. It has definite usefulness in many situations in which susceptible persons are exposed to infection, but its exact field of usefulness and limitation has not been fully defined. It is believed that to date there has been no reliable study of

sufficient duration to permit a precise evaluation of the effectiveness of vaccination over long periods. For that reason it was deemed unwise at present to make the BCG available for general distribution in this country.

Until the optimum methods of using this vaccine are defined and the exact field of usefulness and the limitations have been established, it seems best to limit its use and distribution to the controlled studies in which careful observations and prolonged follow-up examination by experts are possible. In this manner the best available information concerning the uses and limitations of BCG vaccination can be obtained and its field of usefulness can best be delineated.

In accordance with this policy plans for a BCG vaccination program in the city of Boston are under preparation by the Division of Tuberculosis of the Boston Health Department. Vaccine, according to recent advice from the Department, is to be furnished by the Tice Laboratory of Chicago, and the technical application of the program will be initiated by an associate of that laboratory and will be conducted as recommended in the report of the Chemotherapy Committee of the American Trudeau Society.

## NURSE RECRUITMENT

THE National Student Nurse Recruitment Committee, with headquarters in Chicago, is soliciting the active co-operation of physicians in its current program. A national campaign is underway, and an enrollment goal of 50,000 new students in 1948 has been established.

An impressive list of sponsoring agencies includes the American Hospital Association, the American Medical Association, the American Red Cross, the American College of Surgeons and the United States Public Health Service.

A profession for women needs constant replenishment of ranks that are undergoing constant depletion. In other professions such as

medicine, law and engineering, engaged in largely by men, the majority of those embarking on these careers expect to continue in their practice throughout active life. Marriage acts only as an increased stimulus. Matrimony, on the other hand, attractive as it may seem in its various aspects, serves to curtail the years of active practice in a profession whose ranks are largely filled by women.

Despite aspersions that have been cast on the motives of hospitals in soliciting student-nurse enrollments, based on the assumption that these young women are being exploited in the interests of cheap labor—the hospital slave gangs of the la-di-da institutions, as Dr Brady, of the *Boston Traveler*, terms their training—the fact remains that wider horizons are opening up for the thoroughly trained nurse, in administration, in industry, in public health. Bedside nursing is another matter, and to care for the practical needs of the patient it is necessary that another type of nurse be trained according to a less ambitious program.

## MASSACHUSETTS MEDICAL SOCIETY

### ANNUAL GOLF TOURNAMENT

The winners at the annual golf tournament of the Massachusetts Medical Society, which was held at the Woodland Golf Club on the afternoon of May 26 and in which thirty-one physicians participated, were as follows: low gross, R. S. Nugent, low net, T. P. White, and second low net, J. Hammer.

### DEATHS

**GANLEY**—Edward H. Ganley, M.D., of Methuen died on January 23. He was in his fifty-seventh year. Dr. Ganley received his degree from Tufts College Medical School in 1917. He was a member of the staffs of Clover Hill and Lawrence General hospitals and was a fellow of the American Medical Association.

His widow, two sons and a daughter survive.

**SWEENEY**—Bartholomew P. Sweeney, M.D., of Leominster, died on May 20. He was in his sixty-second year.

Dr. Sweeney received his degree from Baltimore Medical College in 1911. He was a member of the American Urological Association and a fellow of the American Medical Association.

Two sons, a daughter and five grandchildren survive.

## MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

### CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The July and August schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows:

CLINIC	DATE	CLINIC CONSULTANT
Haverhill	July 7	William T. Green
Brockton	July 8	George W. Van Gorder
Salem	July 12	Paul W. Hugenberger
Gardner	July 13 and August 10	Carter R. Rowe
Worcester	July 16	John W. O'Meara
Springfield	July 20	Garry deN. Haugh, Jr.
Hyanus	July 22	Paul L. Norton
Fall River	July 26	David S. Grice
Lowell	August 6	Albert H. Brewster
Greenfield	August 9	Charles L. Sturdevant
Pittsfield	August 18	Frank A. Slowick

Physicians referring new patients to clinics should get in touch with the district health officer in making appointments. Patients are seen by appointment only.

### CLOSING DATE FOR AUTHORIZATION OF PAYMENTS IN EMERGENCY AND INFANT CARE PROGRAM

The federal Government has ruled that payment for maternity care may not be authorized after June 30, 1948, even though the patient was eligible for payment for such care prior to July 1, 1947.

If there are any such cases pending, the necessary application must be submitted at once to the office of the Department of Public Health, Division of Maternal and Child Health, 73 Tremont Street, Boston, to allow time to clear questions and to issue the authorization papers before June 30.

## MISCELLANY

### BCG VACCINATION

The following report was submitted to the Executive Committee of the American Trudeau Society, medical section of the National Tuberculosis Association at its meeting in Chicago on January 22, 1948, by Dr. H. McLeod Higgins of New York City, chairman of the Chemotherapy Committee and was adopted by the Executive Committee.

The members of the Society and other physicians in the United States have been interested for many years in active immunization against tuberculosis with BCG. The campaign of public-health activities in the field of tuberculosis control by official and voluntary agencies and the acquisition of new knowledge concerning immunity in tuberculosis have prompted the American Trudeau Society to make the following observations and recommendations:

BCG vaccine, prepared under ideal conditions and administered in tuberculin-negative persons by approved techniques, can be considered harmless.

The degree of protection reported following vaccination is by no means complete nor is the duration of induced relative immunity permanent or predictable. The need for further basic research on the problem of artificial immunization against tuberculosis is recognized and is to be emphasized. Studies should be directed toward the improvement of the immunizing agent, the development

of criteria for vaccination and revaccination and the more accurate determination of which groups in the general population should be vaccinated. Several well controlled studies are under way at the present time, and it is expected that others will begin in the near future.

On the basis of studies reported in the European and American literature, an appreciable reduction in the incidence of clinical tuberculosis may be anticipated when certain groups of people who are likely to develop tuberculosis because of unusual exposure, inferior resistance, or both, are vaccinated.

In the light of present knowledge vaccination of the following more vulnerable groups of persons is recommended provided they do not react to adequate tuberculin tests: doctors, medical students and nurses who are exposed to infectious tuberculosis, all hospital and laboratory personnel whose work exposes them to contact with the bacillus of tuberculosis, persons who are unavoidably exposed to infectious tuberculosis in the home, patients and employees of mental hospitals, prisons and other custodial institutions in which the incidence of tuberculosis is known to be high, and children and certain adults considered to have inferior resistance and living in communities in which the tuberculosis mortality is unusually high.

Vaccination of the general population is *not* recommended at this time except for carefully controlled investigative programs, which, as a rule, will be best carried out under the auspices of official agencies such as the United States Public Health Service, state and municipal health departments and other especially qualified groups.

BCG vaccine should not be made available for general distribution in the United States at present because the most effective strain of BCG has not been agreed upon nor has fully satisfactory standardization of the vaccine been achieved, the best qualified experts have not agreed about the most effective method of vaccination, and fully satisfactory arrangements have not been perfected for transportation and storage of the vaccine.

The vaccine should be prepared only in accredited laboratories especially devoted to this task, in which virulent tubercle bacilli are not cultivated or handled and in which all other possible precautions are exercised to assure safety and quality of the product.

Adequate record systems should be devised for management of the statistical problems involved in recording and following large numbers of vaccinated people. These and other problems of particular importance are now being studied on an extensive scale by official and voluntary agencies in the United States and in close collaboration with European scientists experienced in this field.

The Society believes that since BCG vaccination affords only incomplete rather than absolute protection, the most effective methods of controlling tuberculosis in the general population are further improvement of living conditions and general health, reduction of tuberculous infection, which can be accomplished by modern public-health methods and the unremitting search among presumably healthy persons for patients with infectious tuberculosis, prompt and adequate medical and surgical treatment of patients with active disease, segregation and custodial care of those not amenable to accepted forms of therapy and adequate rehabilitation.

Fortunately, great advances have been achieved during recent years in the development of diagnostic methods applicable on a mass scale, and there have been significant improvements in the surgical and medical treatment of tuberculosis. The expansion of modern diagnostic, therapeutic and rehabilitation facilities is required to make full use of these new methods, which can accomplish further dramatic reduction of tuberculosis mortality and morbidity in the United States.

It is to be emphasized that BCG vaccination must not be regarded as a substitute for approved hygienic measures or for public-health practices designed to prevent or minimize tuberculous infection and disease. Vaccination should be regarded as only one of many procedures to be used in tuberculosis control. Vaccination seems unwarranted in areas in which the tuberculosis mortality rate is extremely low and in localities in which the tuberculin test is of especial value as a differential diagnostic procedure.

## CORRESPONDENCE

### CORRECT DOSAGE OF CURARE

*To the Editor* I should like to call your attention to an error in the designated d-tubocurarine chloride content of the oil and myrcin preparation in the article by Drs Kuhn and Bickers, entitled "An Evaluation of Curare in Spasticity due to Spinal-Cord Injuries," which appeared in the April 29 issue of the *Journal*. The amount as given, 175 mg of d-tubocurarine chloride (per cubic centimeter), should be changed to 175 units of d-tubocurarine chloride (per cubic centimeter), the actual weight of d-tubocurarine chloride is about 27 mg per cubic centimeter in d-tubocurarine chloride in oil and myrcin (Squibb).

This error is a natural one, arising from the use of milligrams and units interchangeably by clinicians in references to curare dosage of intocostin in the literature, because in the development of this product the unit was originally defined as the curare activity equivalent to that of 1 mg of a particular curare powder previously employed as the standard. The physiologic activity of 1 unit of curare activity is still essentially the same, but 1 unit is now designated as the curare activity equivalent to that of 0.15 mg of crystalline d-tubocurarine chloride (pentahydrate form). Since, on this unitage basis, 10 mg of d-tubocurarine chloride (pentahydrate) has about 66 units of curare activity, it would be exceedingly dangerous to interchange units and milligrams when one refers to the dosage of this compound either in aqueous solutions or in oil-wax preparations.

### SKEPTICISM ON VENEREAL-DISEASE CONTROL

*To the Editor* The editorial entitled "Venereal-Disease Control," which appeared in the May 27 issue of the *Journal*, praises "the remarkable drop in the incidence of venereal disease during 1947" in the United States Army.

Perhaps I am quite mistaken, but I tend to view with considerable skepticism any report that venereal-disease rates could be decreased 40 or 50 per cent by any "intelligent appeal to the higher moral sense of the individual," and although I realize that you are much better informed than I am on this subject, I hesitate to share your enthusiasm for the new program. Before I agree with your viewpoint I would like to know how much of the venereal disease that is occurring in the Army at present is actually being reported and treated by the Army. In view of an increased rate of venereal disease treated by civilian doctors during the same period one is inclined to question just how many of the Army's patients with venereal disease are being driven to civilian doctors by the so-called "new program."

Although I was in the Navy and not the Army during the past war, the efforts of the armed forces to deal frankly and openly with the venereal-disease problem seemed very encouraging, and the training films were an outstanding contribution to both prevention and control. Although I agree with you that moral and spiritual factors should not be overlooked in syphilis, I feel that overemphasis combined with punishment of any form will only serve to drive the disease "underground" and undo all the fine work done by medical officers during the war.

On more than one occasion during the war various units of the armed forces made similar claims in reduction of venereal disease by means of "appeals to morals," which were backed by various means of punishment of the unfortunate soldiers who were victims of the disease. In several cases it was discovered, however, that local doctors were doing a rushing business in treatment of servicemen who did not dare to report their infections.

Are you sure that the Army has made a step forward?

No Test Tubes No Measuring • No Boiling

Diabetics welcome Spot Tests (ready to use dry reagents) because of the ease and simplicity in using. No test tubes no boiling no measuring just a little powder a little urine—color reaction occurs at once if sugar or acetone is present

**Galatest • Acetone Test (DENCO)**

FOR DETECTION OF  
SUGAR IN THE URINE

FOR DETECTION OF  
ACETONE IN THE URINE

SAME SIMPLE  
TECHNIQUE FOR BOTH

1. A LITTLE POWDER

2. A LITTLE URINE

COLOR REACTION IMMEDIATELY

A carrying case containing one vial of Acetone Test (Denco) and one vial of Galatest is now available. This is very convenient for the medical bag or for the diabetic patient. The case also contains a medicine dropper and a Galatest color chart. This handy kit or refills of Acetone Test (Denco) and Galatest are obtainable at all prescription pharmacies and surgical supply houses.
